THE DEATH OF SIR WILLIAM LAWRENCE, BART., F.R.S. —The London *Telegraph* announces the death of this distinguished surgeon, at his residence, Whitehall Place, on the 5th instant. The deceased was born at Cirencester, on the 16th of July, 1783, and was, therefore, eighty-four years old at the time of his death. He received a preliminary education at a classical school near Gloucester, and was afterwards apprenticed to the celebrated Abernethy. So decided was his zeal in anatomical pursuits, that before three years of his apprenticeship had expired he was appointed Demonstrator of Anatomy at St. Bartholomew's Hospital. He finished his professional education, and became a member of the Royal College of Surgeons on the 6th of September, 1805; was appointed Assistant Surgeon to St. Bartholomew's Hospital in March, 1813, and succeeded to one of the principal surgeoncies in May, 1824. He had previously been chosen one of the Professors of Anatomy and Surgery to the College of Surgeons, and delivered the lectures there for four years. For several years Mr. Lawrence lectured on surgery at different medical schools, his celebrated lectures on Physiology, Zoology, and Natural History of Man giving rise to the charge of materialism, as well as being the subject of severe criticism. The Governors of the Royal Hospitals at Bethlehem and Bridewell requested the author either to resign his appointment as surgeon of those institutions or to retract his convictions. In compliance with this demand he wrote a long letter expressing regret at having given utterance to the pernicious doctrines contained in the lectures, the published copies of which he afterwards sold to a London publisher for exportation to this country. In 1826 the deceased made himself conspicuous in his opposition to the Council of the Royal College of Surgeons, although two years subsequently he became a member of the same Council, having been elected to fill a vacancy occasioned by the death of Sir P. M'Gregor, and in 1840 was promoted to a seat in the Court of Examiners. Sir William Lawrence, who was a member of many learned and scientific societies, both at home and abroad, had obtained the highest honors which can fall to the lot of a surgeon. In addition to those already mentioned, he had been twice elected a President of the Royal College of Surgeons, viz. in 1846, and again in 1855. On the passing of the Medical Act, and the institution of a Council of Medical Education and Registration, Sir William was nominated by the Crown a member of that body. He was the senior sergeant-surgeon of the Queen, and only a few months since was created a baronet. By his decease there is a vacancy in the Council of the College of Surgeons. The deceased Baronet leaves a son, who is a member of the College of Surgeons, and medical officer in the Queen's Indian army, as well as two daughters.

THE CHOLERA.

IN EUROPE.—The official accounts of the cholera in Sicily, dated Palermo, the 29th of June and the 4th of July, report as follows: In the province of Girgenti, from the 18th to the 27th of June, 2,573 attacks and 1,371 deaths; Caltanisetta, from the 17th to the 27th, 1,305 attacks and 762 deaths; Trapani, from the 19th to the 27th, 17 attacks and 13 deaths; Catania, from the 23d to the 28th, 107 attacks and 55 deaths. For the week ending July 4, for the provinces of Catania, Caltanisetta, Girgetti, and Trapani, the attacks were 2,383 and the deaths 1,421. Palermo and Messina enjoy perfect health, and both have established cordons against infected districts.

IN THE UNITED STATES.—The cholera appears to have manifested itself decidedly among the troops at Fort Larned and Dodge, and still prevails at Fort Harker, all of which are stations upon the great "plains," or prairies of the West, and designed more particularly as defences against Indian depredations. Exchanges say "it is raging fearfully in Ellsworth, Kansas, the average mortality being ten a day. The place is almost completely deserted."

A telegram has also been lately received at the War

Department from Fort Leavenworth, Kansas, announcing the death of Lieut.-Colonel George M. McGill, Assistant Surgeon United States Army, by cholera, near old Fort Lyon, Colorado Territory, on the 20th ult. The telegram also stated that two companies of the Thirty-eighth United States Infantry passed old Fort Lyon on the 22d ult., and reported having had twenty cases of cholera and seven deaths up to that time.

Another account states that "seven cases occurred in one family at Salina, Kansas, which resulted in three deaths."

In the lower grounds of the Mississippi Valley, particularly in the region of broken levées and neglected agricultural interests, the pestilence has likewise reared its head. The same is true of Arkansas, the plantations in the vicinity of Pine Bluff, Des Arc, and Helena having been sorely visited. A planter at the latter place lost twenty-five hands in one week. The mortality from the disease at Memphis, Tenn., at one time reached as high as fifty per day, but has since visibly declined.

In our own city there have been no importations from abroad, although a few cases have been returned to the Health Board, not all of which, however, were regarded as authentic.

MAISONNEUVE'S OPERATION FOR FISTULA IN ANO.—The method of operating is as follows:—The patient is placed upon the side in which the fistula is located, while an assistant elevates the opposite buttock. One of the extremities of a wire is passed into the external orifice of the fistula, and brought out with the finger of the surgeon, previously introduced by the rectum. The two extremities of the wire are then attached to the two branches of the *écraseur*, and by a rapid turning of the screw the tissues are quickly bound and crushed by pressure. The dressing used consists simply of charpie saturated in a solution of phenic acid (one part in a hundred) repeated once daily.—*N. O. Medical and Surgical Journal. Richmond Medical Journal.*

M. NÉLATON has recently been named a member of the Institute, and has also received from the hands of the Prince Imperial of France, his distinguished patient, the insignia of Grand Officer of the Legion of Honor. On the latter occasion he merely called upon the Prince at St. Cloud, to pay him his usual visit, when his young patient said to him, "Wait a little, doctor, I have something to give you." He then presented the cross and ribbon to the surgeon, saying, "It is not quite new, as my father has worn it for some time." M. Nélaton immediately drove to the Tuileries to thank the Emperor. His Majesty confirmed the welcome fact, and added, "I shall never forget, doctor, the care which my son has received from you." It would seem impossible to confer a signal favor with greater delicacy and grace. M. Rayer, formerly Dean of the Faculty, is the only other member of the medical community in France who has been invested with this high honor.

TRAINING THE YOUNG.—Let us here for a moment linger on the question, what would happen to a young horse if we were to work him in a cart as soon as he was one year old, or if we attempted to train a puppy as soon as it could see. The result would certainly be more likely to produce death than a vigorous adult age. In like manner, the "forced" intellect soon dies out, and if the prodigy of the youthful nursery survives to be a man, he is mostly the biggest fool of the family—while he, who from being the greatest dunce was let alone while young, developes into the sensible, thoughtful, and plodding man.—DR. INMAN. *London Medical Mirror.*

PHOTOGRAPHS OF THE PRESIDENTS AND ACTING PRESIDENTS OF THE AMERICAN MEDICAL ASSOCIATION.—It will be recollected by our readers that at the last meeting of the American Medical Association, Prof. Alden March, of Albany, presented to the association a photograph of all the presidents of that body, which he had taken great pains to collect. We have recently received a complete set of the above, twenty-one in all, which have been admirably reproduced by Messrs. Jeffers & McDonald, of 519 Broadway, Albany. We are glad to learn that Prof. March having generously supplied them with the negatives, they are enabled to supply the profession at a moderate price. The collection is an exceedingly valuable one, as many of those representative men have passed away. The likenesses are truthful and well executed.

IS MY CONSULTING PHYSICIAN A GENTLEMAN?—Dr. U. R. Milner, of Jefferson City, La., in a communication to the *Southern Journal of Medical Sciences* "on the Professional Manners of Physicians," makes the following remark, which, unfortunately for the profession, is a well deserved reflection upon the character of many a consulting physician. "It is a bane of the profession, and a fact attested by the experience or observation of every member of it, that at this day consultation, which is a most valuable auxiliary to successful practice, and when properly conducted and appreciated, an invaluable boon to afflicted man, is made, eight times out of ten, the opportunity of one party or the other to injure the other either by insinuation of some sort or by downright slander. What manners! And what is the effect? Consultations are shunned and ignored, and a general distrust is engendered. If a high-toned, honorable gentleman and doctor is forced to have consultation, and some one is proposed and preferred by the individual or family whom he does not know, the first question he asks himself is, 'Is he a gentleman?'"

CONSANGUINEOUS MARRIAGES.—Dr. Robert Newman, of this city, having been appointed at the late meeting of the "Medical Society of the State of New York," upon a Committee to investigate and report upon the result of consanguineous marriages, asks of his professional brethren answers to the following questions, which may be transmitted to him, 118, West Houston street, before November next: Name (initial) and age of husband, nativity, age when married, constitution, health, deformities, peculiar diathesis, health of his family, hereditary diseases, deformities, &c., Name (initials) and age of wife, nativity, age when married, constitution, health, deformities, peculiar diathesis, health of her family, hereditary diseases, deformities, &c. How are the parties related to each other? How long married? How many children, or sterility? Abortions; cause; how many, and at what period? Children died, at what ages and from what diseases? The constitution, age and present health of living children, deformities, mental conditions, idiocy, cretinism, deaf, mute, blind, epilepsy, albinism, insane, &c., Remarks and other information.

It will be seen that these questions are very comprehensive in their scope, and as answer accurately given will help to clear up many unsettled points we hope all who are able to give him any information, especially those residing in this State, will do so in the assurance that the material furnished will be properly used.

A NEW ITEM IN A BILL.—One charge in a lawyer's bill against a client was, "For waking up in the night and thinking of your business—five dollars." How many such items could with equal propriety find their way into the bills of the physician?

Original Communications.

SOME CONSIDERATIONS IN REGARD TO THE TREATMENT OF HIP-JOINT DISEASE.

By CHARLES F. TAYLOR, M.D.,
OF NEW YORK.

The question is often asked me, "What is your experience in the use of the splint in hip-joint disease?" "Do you find the results as satisfactory as we have been led to expect by those who have been the chief advocates of the counter-extension plan of treatment?" These questions not only evince a disappointment in practice with the splint, but imply a doubt as to the principles of treatment. Not long ago an eminent surgeon who has had abundant opportunities for witnessing the results of the *splint* treatment as practised by a prominent advocate expressed to me his entire disbelief in its efficacy.

My own experience with this mode of treatment having been entirely satisfactory, I propose to give some reasons (as they appear to me) for the frequent failures in its use, together with my own method of procedure.

I believe that the majority of failures in the use of the counter-extension splint are owing to the inefficiency of the instrument employed, and to a practical disregard of the true end to be sought by its use.

An apparatus, like a remedy, should be the embodiment of an *idea*. In the making up of a prescription, or the construction of an apparatus, every element should contribute to the completeness of the whole. We may have antagonistic mechanical forces as well as incompatibles in drugs. In proposing any medical means we should ask ourselves—1st. "What is the ultimate object to be accomplished?" 2d. "What are the simplest means of accomplishing the object?" 3d. "What are the elements which contribute towards the end sought?" 4th. "What are the elements which may interfere with that end, or which may be incompatible with it?"

We must correctly answer these questions before we can reach general success in a proposed treatment.

Let us analyze the objects to be secured by the counter-extension splint.

Dr. H. G. Davis first devised "the splint." The object was *counter-extension with locomotion.*

Simple counter-extension had been used before. Locomotion would secure for the patient fresh air, exercise, appetite, digestion, health, *provided* the splint were sufficient to arrest the disease. In Dr. Davis's hands we will say it has been thus efficient. But his instrument contained several elements incompatible with the main object sought—efficient counter-extension—and which interfered with its success in hands not accustomed to overcoming the difficulties inherent in the apparatus.

In the old splint the ligaturing of the thigh by the perineal strap made it always difficult, and often impossible for the patient to bear sufficient force to accomplish the purpose in view. This was partially remedied, however, by the cross-piece and joint proposed by me, and which have been universally adopted.

Again, "continued *elastic* extension" contains an almost fatal element. "*Elastic*" (India-rubber "elastic") extension is incompatible with muscular extension. If the muscles overcome resistance they are not extended. If the resistance is so great that the muscles are obliged to yield, then the extension is *not* "elastic" to the muscles, whatever it might be to a greater force. "Elastic" extension applied to muscles is an absurdity. Either the resistance is so great that it requires more than the force of the muscles to cause it to exhibit its elasticity when it is *not* elastic to the force the muscles possess, or the elasticity of the rubber yields and the *actual* resistance is made by the webbing surrounding the rubber. In either case the *actual* resistance is non-elastic. But even if elastic resistance were not incompatible with muscular extension, it would be rendered so by the incompetency of the material used. India-rubber has no definite resisting force except under compression and equable temperature. But India-rubber strings incorporated in webbing become softened and attenuated by the heat of the body, and do not retain for many minutes the resistance they had when applied. It is its wonderful facility for becoming stretched-out and utterly useless which makes success of comparatively easy attainment with the use of rubber. So much for "elastic extension" in overcoming muscular action. In regard to its effect upon the diseased joint it is even more ineffective for good.

The splint is used in preference to confinement with the weight and pulley, on the theory that it gives equal protection and immunity to the joint with the advantage of fresh air and exercise. But how can it protect the joint if the extension be elastic? Whenever the force of progression happens to be for the moment greater, then the extension suddenly yields and ceases to afford protection at the very time when it is most needed. Hence the joint is liable to successive concussions with the varying force thrown upon the unequal resistance.

Here, also, the only salvation is the fact that the rubber straps soon stretch out and become, in effect, inelastic.

The simple truth is that muscles yield readily to firm, unyielding resistance, and this only should be used to overcome their action.

Thus much for some of the elements operating at the pelvic end of the splint.

The lower end is attached by adhesive straps. I will not discuss the plan of making traction on from the foot, because I cannot see how such a plan could be seriously adopted. Its inefficiency must be apparent.

Shall motion be allowed at the knee—in other words, shall the instrument reach to the knee, or to the ankle? In 1860, before I had ever treated a case of hip disease, my attention was called to the subject in consequence of the discussions going on at the time. I then devised the short instrument, which has since, for some unaccountable reason, been labelled with Dr. Lewis A. Sayre's name. Inferring that the length of the instrument, with the preventing of motion at the knee, was for the purpose of securing greater room for applying the adhesive straps, I reasoned that more surface could be found inside the thigh than below the knee, with the apparent advantage of allowing free motion at the knee. A cut of this apparatus was published in the *Medical Times* of July 20, 1861.

My first case satisfied me that my reasoning in regard to it was fallacious. In the first place, experience proves that there are decided advantages, with no important disadvantages, in *preventing* motion at the knee. Primarily it is an advantage (when counter-extension is complete, *but not otherwise*), to cause the motion of progression to be at the hip instead of the knee, as it would be if the latter were not confined. Again, it is utterly impossible to keep on the adhesive straps while the muscles of the thigh—an inverted cone itself—are alternately shrinking and swelling beneath them in moving the leg. The straps will slip off.

Dr. Prince says it is a "beautiful little instrument;" and so it is; but it is good for nothing, being practically inefficient except with an amount of attention seldom given any case. I did cure one case with it, but I saw my patient daily for months, and the waste of adhesive plaster was enormous.

Another serious objection to the short instrument is, that it is impossible to secure so good extension of the thigh upon the pelvis: that is, the flexor muscles cannot be so well extended as they can be with the long splint. But even with the long splint we have this disadvantage, viz. that the adhesive straps will yield, relax, and slide more or less, requiring constant watching and re-adjustment of the apparatus; and this is particularly the case where the patient is allowed to walk about.

In such circumstances the adhesive straps must not only keep up extension, but are forced at each step to bear the weight of the body in addition. A slight relaxing of these straps taking place, there is no more extension; and as they always do relax or slide more or less, let me ask here, what becomes of the theory that the head of the femur is partially "drawn out" of the acetabulum? Is the relief derived from the splint in consequence of this alleged fact? What with the relaxing of the adhesive straps and the "elastic" extension, we should have a continual churning motion in the socket which would not be very favorable, one would think, to the diseased joint!

Employing more force in these cases than practitioners generally do, I am yet incredulous about the alleged "drawing out" of the head of the bone. I do not believe it occurs, or ought to occur, nor do I believe that it would be anything but harmful if it did occur.

The sole object of counter-extension is to destroy the tonicity of the muscles about the hip-joint. This destruction of tonicity gives relief and motion, and is all we can do by mechanical means for this disease. If we can do it, and still allow the patient fresh air and exercise, so much the better. And this should be our aim, and until we have fully accomplished it, we have not realized the benefit of counter-extension treatment at all. If a splint or weight be applied it may assist in keeping the limb steady and quiet, and in that way the patient may improve; but the improvement is due to the confinement and protection *from* motion, rather than to counter-extension *and* motion, which latter are the two sources of benefit when counter-extension is efficient. I repeat, the *muscular tonicity must be temporarily destroyed.* The counter-extension must be carried to that point.

And here we have a certain guide as to the amount of force to be used and the extent to which it is to be carried. When we have destroyed tonicity, our chief labor is done. Afterwards we need only use force enough (which will be relatively small) to keep up the flaccid condition of the muscles till the disease subsides. We might even temporarily dispense with the splint altogether, except that when the extension is entirely suspended the muscles quickly recover their tonicity; and, besides, the weight of the body would not be supported in locomotion if the splint, or some form of crutch, were not used. This explains how a case may progress favorably with the unequal extension which is inevitable with the splint, provided the muscles have first been relaxed by diminishing their tonicity. In such cases we do not have those contractions which are apt to follow (even when they are prevented from accompanying) the active stage of the disease. It may be, and generally is, followed by weakness of the muscles about the joint, which may require special treatment to restore their tonicity. This is a sacrifice we must make to the greater good of arresting the diseased action in the joint. On the other hand, if contractions accompany or follow the disease, we may be sure that our counter-extension has been inefficient, and therefore worthless *as* such; and that the improvement, if any, is due to the quiet fixation of the joint, which the splint has been a convenient means of accomplishing. And I suspect this is very often the case in the use of both splint and pulley.

I have mentioned as one serious objection to the *short* splint, the impossibility of acting adequately on the flexor muscles. Both long and short splints possess a grave fault, in the impossibility of acting on the adductor muscles. In fact, the position of both on the outside of the leg rather favors adduction of the leg, and there certainly is no possible way of specially extending the adductor muscles, the ones most particularly influenced by contractions. They can simply extend in the direction of the thigh, acting with equal force on the already extended, as well as contracted, muscles. They do not sufficiently tend to correct deformity after it has begun; hence a great deal of force used is wasted, from the sheer impossibility of actually antagonizing a contracted muscle.

Now, if we could bring our force to act directly on the contracted muscles (the adductors, for instance), a relatively small amount of force would overcome them, and the point would be gained at once, for the other muscles are already extended by their position. Hence I have used for several years an apparatus with *two* perineal bands. The "cross piece" at the top is carried nearly around the pelvis to the opposite side, so that it becomes a hip-*band.* The steel is extended far enough for fastening to it the perineal strap—about three-fourths of the circumference of the hips—and terminated by a leather strap. Sometimes there is an abduction screw at the joint, between the hip band and splint, but experience proves that all the motion required can be secured by regulating the perineal straps. Tightening the opposite strap would of course abduct the thigh and act directly on the adductor muscles. By thus having every action of the joint under control of the instrument, we are enabled to accomplish a *definite* purpose and secure better results with less force.

There is another great advantage in having two perineal straps. The danger of abrasion of the skin is diminished more than one-half, and if it should become sore we can loosen, or even take off, the strap of one side, the action of the instrument being temporarily kept up by the other strap. We thus add to our resources against accidents.

This arrangement of double perineal straps (and, when necessary, abduction screw) seems to make the upper end of the splint very satisfactory, if not perfect in its action, for it enables us to realize without delay or indirection the object of the treatment—the reduction and often temporary destruction of muscular tonicity, *especially of the muscles most contracted.* But there is still the difficulty of keeping up sufficient uniformity of extension, especially with active patients, after the subsidence of the acute symptoms.

In spite of the utmost care there will be motion at the lower end of the splint, and a tearing loose of the adhesive straps at the bottom, which, with the frequent want of care on the part of the patient's attendants, after improvement seems to be assured, causes a liability to too much concussion in the joint, and a regaining of tonicity of the muscles and thus hindrance to the most favorable progress of the case. Still there is not so often actual recurrence of the disease, once

subdued, as prolonged recovery with chronic irritability in the joint, as shown by lingering tendency to contractions of the muscles. While the patient is quiet, there is not the least difficulty in accomplishing all that is desired with the splint just described. Only when the patient throws his weight upon the splint in walking do we find the adhesive straps insufficient to resist for any length of time the severe and unequal strain thus thrown upon them.

In other cases, as disease of the knee and ankle, and dislocation of the hip-joint, I have been in the habit of using what may be called the *expectant* treatment. A simple apparatus is made, attached to the shoe and extending to the perineum, where it terminates in a well padded crutch, turned outward so as to rest under the ischium. The apparatus is made a little longer than the leg—with a contrivance for extending when needed—so that in standing or walking the heel never reaches the ground, and of course the whole weight of the body rests on the instrument. The patient then has motion of the joint, but no weight is thrown upon it. The result of this protecting, expectant treatment, has been so satisfactory, that it suggested the idea of incorporating it with the counter-extension hip-joint splint. The result is shown in the accompanying figure. The splint is

extended to the bottom of the foot and turned under it, from which position extension is made. Adhesive straps are applied to *both sides* of the *whole* leg, in the usual manner, the inside strap terminating in a buckle (*a*) and the outside strap terminating in a short piece of webbing, which is passed through a slit in the apparatus, thence under the foot through another slit (*c*) at the end of the foot piece, and buckled to the inside strap just above the internal malleolus. Thus extension is made from the bottom of the foot. Thus, also, when the patient attempts to walk it is the instrument which strikes the ground and sustains his weight, without in the least increasing the strain on the adhesive straps. In fact it is an ever present crutch, allowing motion of the joint, but not allowing weight to be borne on it. Extension is kept up continually, more surface is allowed for the adhesive straps, and only the legitimate strain is ever thrown upon them—that which antagonizes muscular action—but never the weight of the body. There is one other advantage which this instrument has over others. Usually we have to depend much on the care and judgment of others—the patient's parents, friends, and nurses. With the splint terminating in the middle of the leg there is no definite point where it should be, and hence no guide to the eye or definite indication by which inexperienced persons can know if the apparatus is properly acting. Hence the difficulty of getting the most careful directions carried out. But by the crutch and extension splint combined, the patient himself knows at once if the instrument is acting or not. The least slipping or relaxing of the straps makes it longer under his foot, and impedes his walking, and he desires it readjusted. But even if it were not actually extending the hip—and after the tonicity of the muscles is once overcome, it often need not—the patient is entirely safe from the pressure of weight and concussion in the joint. He walks, but the leg hangs suspended. Indeed, many have advised, as I sometimes have when circumstances were such that nothing better could be done—patients to wear a thick sole on the foot of the *well* leg and use crutches, letting the lame leg hang. The only difficulty is in carrying the plan into practice with sufficient perseverance and uniformity. If the crutch can be attached to the leg as in this instrument, and concealed from view, and always ready with its protection, the results of the expectant treatment might be better.

One word about applying adhesive straps. I have seen several legs irretrievably spoiled by applying the straps on the leg only, neglecting to include the thigh. This has generally been done where the treatment had been by the weight and pulley. Force enough to relax the powerful muscles about the hip-joint must be liable to pull asunder the weaker ones at the knee and ankle, if traction be made only from the foot or leg. I have seen great injury result from such thoughtlessness, the patients recovering from the hip disease only to find themselves crippled for life with knees so weakened as to be wholly unable to sustain them. Under all circumstances the straps ought to embrace as much of the thigh as possible. Let no one understand me as intimating that with the best appliances disease of the hip-joint is easy to cure, or to treat. Not so. Success is only to be obtained—I mean the best success, which is the only result we ought to be satisfied with—by diligence, care, and perseverance.

A perfect splint, even if that were attainable, is not enough. There is no magic in surgical apparatus, let them be never so cunningly devised. They should have a function corresponding to our idea of the requirements of the case. Unless we diligently attend to little details, we cannot expect the best results. Success is generally in the ratio of our efforts to secure it.

Intestinal Absorption.—According to Letzerich (*Virchow's Archiv*, xxxvii. 232), fat and albumen are not absorbed by the epithelium of the intestine, but by vacuoles between the epithelial cells, which lead directly from the intestine into the lacteals. Fat in the epithelium he considers pathological, and generally due to excess of fat in the food.

THE PROTECTIVE USE OF QUININE.

By STEPHEN ROGERS, M. D.

NEW YORK.

It must have been brought home to the appreciation of most people, who have devoted their time and brains to the investigation of any subject, that popular errors relating to that subject,—and having their origin in the published conclusions of unqualified observers, or observers of too limited experience—are most obstinate things to overcome. The practical confusion which one witnesses in the popular, as well as the professional mind, resulting from these publications, is often vexatious and disheartening to the studious investigator and author.

These reflections were again called forth by the perusal of an extract from the *Nashville Journal of Medicine and Surgery*, published in the RECORD of July 15, under the title of "Quinine as a preventive of malarial fever."

As that extract contains unwarrantable statements, is too indefinite and confused to serve as a guide to either practitioner or layman, and is therefore, in my opinion, a dangerous piece of medical literature. I offer you the following extract from my memoir upon the uses and virtues of quinine, published in the *Transactions of Medical Society of the State of New York for* 1862. I therein treat of the uses of quinine in miasmatic disease in the following order, viz. first, its protective uses; that is, to protect from miasmatic infection. Second, its preventive uses; that is, to prevent paroxysms of miasmatic disease after infection has taken place. Third, its curative uses; that is, to cure miasmatic disease during the paroxysm. As your published extract from Dr. White's report involves the principles set forth in my first subdivision, I send you that portion only which reads in substance as follows:

Among the first, if not *the* first danger the emigrant is exposed to on his arrival in a miasmatic locality, is that attending the fever known by the various names, remittent, bilious remittent, climatorial, acclimating, climatic, and, as I prefer, *first miasmatic fever.*

Consequently, the first, the invariable, and the inevitable inquiry is, what can be done to avoid it? And eminently proper are such inquiries, for, with comparatively rare exceptions, the paroxysms of this first miasmatic fever are by far the most severe and immediately dangerous of any the individual will ever suffer however long he may remain in the unhealthy region.

This is *the* fever which, both in the West and in the East Indies, in Africa and in tropical America, has given the terrible character to tropical fevers which is pre ty universally entertained. It is of paramount importance then for the recently arrived resident to adopt all possible means to escape this particularly dangerous first attack. But the query arises, as he is to become a permanent resident, will he not sooner or later certainly suffer his first and severe type of fever?

The law relating to this first miasmatic fever, is similar to, or identical with that observed by yellow fever, viz. the longer one resides in the locality where it is suffered, the less liable he becomes to it, so that while in the case of yellow fever he may escape it altogether, in miasmatic disease, though he may at a later date suffer mild paroxysms often, yet the first violent climatorial attack he escapes altogether.

In both cases a species of toleration of the surrounding influences is acquired, their poisonous impression upon the sensorium is lessened; so that in the one case the disease is escaped altogether, and in the other the intense and destructive character of the paroxysms of the early attacks is not witnessed, except in rare cases.

This fact was stated by Dr. James Johnson, to be the result also of a continuous high temperature; and he attempted to employ this opinion in explanation of the fact that Europeans do not suffer yellow fever in the East Indies, they becoming "seasoned," as he termed it, by the long sea voyage in the tropics.

Recorded experience, however, destroys this argument of Dr. Johnson. I am acquainted with the fact that persons who have crossed the tropics twice on the voyage out, and cruised for months in the tropical zone, have still taken yellow fever when exposed in infected localities on the Pacific coast of this continent.

In miasmatic poison, time, as well as infected locality, is also requisite for this acclimating process. How is it to be secured in necessary amount and with any degree of certainty? I do not hesitate to reply, that it can be done by the proper employment of quinine.

Let us not fall into the delusion, however, of supposing that this is an invariably necessary agent; for it is a fact, that time, toleration of the poison, and acclimation, are not infrequently secured without any aid from the medical art. Some favoring circumstances, such as removal from the infected locality during hours of sleep; or short periods of exposure at long intervals; or some peculiar resisting force of constitution, may carry one along for months, and thus secure him a mild miasmatic attack. But quinine, when given in doses sufficiently large to interfere with the depressing influences of the miasmatic poison, will undoubtedly protract the period between the first exposure and the development of the first paroxysm so much, as to secure the constitutional change required for the modification of the febrile symptoms. High authorities have promulgated very confused ideas upon this very point.

For example, the United States Sanitary Commission have adopted the doctrine, that if quinine have not the effect of arresting the paroxysms, "it will always render the disease milder." Now, I believe it does so in an indirect way only, that is, by giving the exposed person time for acclimation, as above explained. I have never had reason to believe that the simple introduction of quinine into the system daily for an indefinite time, is followed by any such modification of the febrile paroxysms necessarily.

Were this the case, persons dosed with this drug for a time before their exposure to the miasmatic poison, would have a mild form of the fever whether they continued to take it after the exposure commenced or not.

I have no knowledge of any experimental observations which tend to establish any such doctrine as this.

My experience in this matter has thoroughly convinced me, that the law is, that the longer the quinine taken enables the person to escape the first miasmatic fever, the more will its paroxysms be modified, and the milder will the attack become. The converse of this would be, that whatever the quantity of quinine taken, should the fever notwithstanding come on early, no such amelioration of its character will be experienced; but it will be in every respect a true acclimating fever.

So uniformly did it result, that the person who—by reason of any of the favoring circumstances herein enumerated—passed a month or two in miasmatic exposure before suffering his first attack, had it in a more or less modified form, that when I saw a person newly arrived in the country, passing thirty or forty days' exposure without symptoms of fever, I could predict with almost absolute certainty that when his fever did come, it would be in a mild form.

Now, the indefinite protection of the person from miasmatic *infection*, and of course the power to postpone in like manner the first attack of fever, is unquestionably possessed by quinine, and this is what should be termed its *protective* action. I now come to the inquiry as to the amount of the medicine required to effect this result. My experience with quinine in the treatment of the developed miasmatic disease had taught me that doses too small to produce a sensible impression upon the nervous system, could not be relied upon to prevent the paroxysms. Why then should such small doses be expected to prevent infection? I could never see any reason for such an expectation, and therefore I applied the same principle to the protection from infection, that I had been accustomed to employ in the prevention of paroxysms. Hence, whether administered for the one object or the other, a sensible impression should be produced, and for the purpose of protecting from infection this impression should be continuously kept up during the hours of exposure.

Appreciable signs of the action of the drug are produced by from three to six grains. My usual first dose was four to five grains, and increased or diminished as seemed requisite in each case. I ascertained that once in about twelve hours was sufficiently frequent to repeat the dose as a rule, though some eliminate the drug completely in about eight hours; and, therefore, such persons should take their dose once in eight hours.*

Now, infection having been avoided by this continuous impression of quinine during the exposure, there seemed to me no reason for continuing its administration after the exposure ceased, and accordingly I so instructed the patients. The result was a uniform exemption from infection. The experiments whose results led me to these conclusions, though extending over a number of years, would have been less conclusive had not an occasional self-willed person declined to take the protective dose, on the ground that well people require no medicine. I will mention but a single case in illustration. A vessel arrived in the port of Aspinwall with a perfectly fresh crew, that being their first voyage to that harbor. Among them were three persons who refused to take the prescribed quinine. After remaining at the wharf about three weeks, the vessel sailed. These three persons, and these only, were taken ill of fever on their way to New York. All the rest of the crew had uninterrupted good health. So many similar cases occurred within my observation during my residence there, that I was compelled to accept the results witnessed as the effects of the measures adopted, and not mere coincidences. I did so, too, with a full understanding of the behavior of miasmatic poison upon a promiscuous population. I knew it to be possible, for I had often witnessed its demonstration, that some may expose themselves for weeks to miasmatic exhalations and yet go away perfectly well and remain so, without ever taking a grain of quinine or other medicine. On the other hand, I had seen persons seriously infected by a few hours' exposure only. While I am ready to admit that many of the persons to whom I gave the quinine would probably have escaped the fever without it, I fully believe that all of those obstinate ones who refused to take it, and suffered fever, would have been protected by it.

This fact of the great difference in susceptibility to miasmatic poison so frequently seen, is not sufficiently considered by most writers upon the uses of quinine, in making up the conclusions to which they have arrived. For example, the Sanitary Commission publishes the story, that seventy-seven persons went on an excursion up a river in Africa, and leaves us to infer that they were gone about twenty-four hours. They all took a dose of quinine when they started, and carried another dose to take at night, except one of the party. This one was the only one of the whole seventy and seven men who suffered fever subsequently. Now, I do not deny that this man may have been infected during that exposure, but if so, he certainly was a remarkably susceptible subject. In my belief, it is scarcely probable that another one of the whole party would have suffered from so slight an exposure, had they taken no quinine. The inference, therefore, that the other seventy-six men were protected by the quinine they took is by no means deducible.

Also the following notable sample of the extraordinary delusions that even physicians are occasionally led into. Thirty-two officers and men were exposed in the Rio Ponga for two days and two nights. They took four grains of quinine daily during the time. Four of the party subsequently suffered fever. On another occasion a party of thirty-four were similarly exposed for seven or eight days, taking a dose of quinine *every other day* only, during the time. Seventeen, or just half of this party, subsequently had *severe remittent fever*, notwithstanding their dose of quinine on alternate days, while twelve and a half per cent. of the former party fell sick after two days' exposure, though they took a daily dose.

No one with any knowledge of the natural history of miasmatic disease as manifested in the human subject can regard this account as affording the least evidence that the quinine given exercised any influence one way or the other. It is not at all probable that one of the whole party was protected by the medicine he took. The result is certainly much worse than the former similar Chagres exposure of so many thousands of our countrymen who took no medicine whatever. The old Isthmus transit used to occupy from one to four days, yet the persons who contracted the fever during it, never amounted to twelve and a half per cent. Obvious therefore as it is to me, that the quinine given in the cases here alluded to was nearly totally useless, my surprise at the conclusion to which the author of the report comes may be understood. He says, "it is not to be presumed that quinine will prevent the occurrence of fever in every case, but in a sufficient number to be of the utmost benefit, and the fever occurring in those who have employed it as a prophylactic is sure to be of little moment." Yet this reporter has just stated that fifty per cent. of his cases had *severe remittent fever* after exposure of one week.

These histories simply demonstrate what I have already declared to be the truth, viz., that there is a great difference in the matter of susceptibility to the impressions of miasm manifest in different individuals—some resisting them many days, as we see in the case of the thirty-four men, half of whom only became infected and suffered disease from a seven or eight day exposure. Others became thus infected in a day or two, and in a few *rare* cases I believe that a few hours' exposure will seriously infect them.

I need not urge the importance of a due consideration of all of these facts, in estimating the effect of the quinine administered in any given case—how much credit should be awarded to the drug, how much to fortuitous or sought circumstances, and how much to the unaided *vis medicatrix naturæ*.

* For further physiological information upon the point of the duration of the influence of quinine, I refer the reader to a Report of the results of experiments, by Dr. Bence Jones, published in the RECORD of Sept. 15, 1865; and to my Letter relating to the same, published in the RECORD of Oct. 15, 1866.

I believe that this point was weighed with due care during the investigations which convinced me that *quinine will protect from miasmatic infection.* This power conceded to it, then very naturally arises the query—*How long may we rely upon its protective powers?* This is a more difficult question to answer than the uninitiated, and even than some of those who have written upon quinine, seem to suppose. Few persons will submit to an interminable drugging, practised, as it must be, in an experiment of this character, while the subject is in perfect health, and on this account, chiefly, I have never been able to form a definite opinion in reply. But whatever the limit may be, I am convinced that we may rely upon it with confidence, for any period within sixty days, and this is long enough for any practical purpose. The various published reports touching the permanency of the influence of quinine, nearly all refer to its action as a preventive of paroxysms, and not as a protective from infection. Of this class was a case quoted by the Sanitary Commission, wherein a period of one hundred and forty days seemed to make no difference in the action of the drug. Though quoted as evidence of its permanent power, this case is worthless upon the point in question. This protective power is of the utmost utility to the transient resident who may desire to get off without carrying with him the poisonous impression which will eventually develop into disease. To this end, where the residence is not to extend beyond sixty days, I recommend that a continuous influence of the quinine be kept up during the whole time, if the exposure is constant, but to be omitted during any period that the person may be removed from the miasmatic atmosphere. Where the residence is to be longer, I can see no useful purpose in continuing to administer the medicine longer than about thirty days, because, as we have seen, a residence of thirty days and upwards in the locality, will have so modified the constitution that his febrile attacks will be of mild type, should they not be prevented by appropriate treatment, a very practicable thing to do. Whether, to secure this result, it is necessary to give sufficient quinine to constantly produce signs of its action or not, I am by no means certain. But as, short of this evident effect, there is clearly much doubt as to whether the medicine is exercising any influence or not, I think it a safe error, if error at all, to be thus far certain, and I therefore so recommend.

Summary: When the person is thrown into miasm, give him at once three to five grains of quinine—according to the effect—and repeat the dose once in *twelve* hours during the whole period of exposure, up to about thirty days in the permanent resident, and to sixty days if the person is not to remain longer than that in the impure atmosphere, and where there are peculiar reasons for desiring him to avoid subsequent miasmatic disease. It should not be lost sight of, that cases often occur wherein it will be necessary to repeat the dose once in eight hours in order to maintain the required influence of the medicine, the signs of which are to be carefully watched and maintained in all cases.

When exposure ceases the medicine is to be at once suspended.

The following additional deductions from the general summary of that memoir, may appear to you of sufficient interest to merit republication, viz. That removal from a miasmatic atmosphere for any twelve hours, especially during a night, is quite equivalent as a protective to one dose of quinine—it may be much more economical, and when practicable, is by far the most desirable protective measure.

That in all cases where this measure can be daily practised, it will unquestionably preserve the susceptibilities of the brain to the action of the medicine, for an indefinite and probably long period, and will thus serve indirectly as a most efficient protective.

That when continuous exposure is inevitable, there is no safety in attempting to protect from infection by the use of quinine for a longer time than two months, and as a general rule it is not advisable for longer than one month.

That ceasing its administration at the end of the first month, by the time the infection takes place and the premonitions appear, the susceptibilities to the medicine will have become so restored, that it will be practicable, generally, to prevent the paroxysms for long periods of time.

That by an observance of these principles, and by avoiding the causes of other diseases, most men, of even ordinary constitutions, can be kept in miasmatic localities for years in an efficient state of health.

INTRA-LARYNGEAL SURGERY,

AND TOPICAL MEDICATION OF THE UPPER AIR-PASSAGES.

By J. SOLIS COHEN, M.D.,

OF PHILADELPHIA.

No. 1.

Professor Czermak, the ingenious founder of laryngoscopy, though not himself a practising physician at the time, soon recognized the fact that the laryngoscope could be utilized for far more important purposes than that of the diagnosis of laryngeal disease; and using his mirror as a "guide to the operating hand," he boldly plunged a sound into the interior of a patient's larynx, and demonstrated a safe practice for the method of intra-laryngeal surgery, with visual confirmation of results. Herein, no one can claim participation in his honors.

It is now practicable to apply local treatment to the upper air-passages, in many instances, with as much precision as to the inner surface of the cheeks or nostrils, and the ingenuity of operators and cutlers has adapted to the purpose instruments of such configuration and mechanism, as permits of the performance of many delicate surgical operations, in the removal of neoplasms especially, under a great variety of form and seat of disease.

The employment of the laryngeal mirror for purposes of diagnosis, is an art comparatively easy of acquisition; but operations within the larynx and trachea by its aid, require considerable practice, if not a certain amount of peculiar adaptation in addition.

Certain general manœuvres are necessary for the proper introduction of every instrument, from a blunt probe to an exposed bistoury. The plan which the writer has found most useful in instructing his pupils, is to begin by holding the mirror over a plane surface, as for instance, the page before us; the paper representing the plane of the upper surface of the larynx, and the mirror being held an inch or more above it, at an inclination of about 45°. Then the student is directed, with the other hand, to take an ordinary probe, and keeping his attention upon the image of the spot he designs touching, to carry the probe towards the mirror until it is nearly in contact, and then to move it gently until a distinct view is obtained of its point, when, without losing sight of the end of the probe, it is to be directed towards the image of the spot selected, and to be slowly carried to it. A little practice will soon render him familiar with the direc-

tion necessary to be given to the probe to secure the desired movement. After this has been repeated sufficiently to familiarize the student with the proper method of following the reflex of his movements, so as to carry his instrument at will to the right or the left, in front or behind, the straight probe is changed for a curved one, such as would be suitable for introduction into the larynx, and the same exercises are repeated, a second person after a while designating the points which the student is to endeavor to touch. A triangular pasteboard tube of the size of the larynx, with certain marks upon its inner surface, is then substituted for the sheet of paper or printed page, and the mirror is then held above it, so as to reflect the image of the interior, and the exercises are repeated. The difficulty of touching a desired spot is now rather greater than before, and the student learns to raise the handle of his instrument, if he wishes to touch the anterior surface of the tube, and to depress it in order to carry the point of his instrument towards the posterior portion of the tube, as also the proper movement to the one side or the other.

After this, a papier-maché model of a larynx is employed as a means of exercise, and, finally, the method introduced by Tobold, which is to mount a recently excised larynx with the tongue, soft palate, etc., upon the rod supporting a skull, with the jaws separated, the œsophagus being fastened round the rod. If a recent larynx cannot be obtained, a wet preparation, or an artificial one is substituted.

After a certain degree of facility has been acquired in this way, it is necessary to learn how to manage the mirror and operating instrument at the same time with artificial light; and this is best done by suspending the model, or the mounted skull, within a box, with a small opening to represent the open mouth just in front and above the larynx, or model; then the light is to be thrown into the interior through the opening, and the manipulation proceeded with as before.

After the student has acquired considerable facility in placing the point of his instrument upon any desired spot, recognized solely by reflection in the mirror, it will require a great deal of patience and of practice to enable him to accomplish the same result upon a patient, in whom nervousness and the natural irritability of the structures will cause more or less movement of the parts, whose reflex must be followed promptly and with accuracy in order to ensure precision of movement. The results that reward perseverance seem all but incredible to those who are not familiar with the subject, or impressed in its favor.

The principal rule to be observed in these manipulations, be they what they may, is to carry the instrument well towards the mirror, until its point is visible in the image, and not to l se sight of the point during the operation. Very often the instrument will have to be withdrawn again and again before a favorable opportunity is presented for carrying it home; but with increased practice, the expert soon becomes able to succeed at almost every attempt.

We can, in this way, not only make local applications of a general nature, such as swabbing, syringing. etc.; but circumscribed ulcers can be cauterized; abscesses opened; tumors ligated, excised, or twisted off; granulations scarified; individual muscles galvanized; everything except dissection; and this without compromising the integrity of the healthy structures, any more than occurs under ordinary circumstances.

The instrument which it is proposed to place within the larynx, must be formed with a proper curve or angle. The angle most generally serviceable is one of 112°, but if it be a little greater or a little less, it will make no material difference. An angular instrument may be employed, if desired, but will occupy more space in the throat than if curved, and thus at times may be less serviceable. The laryngeal portion may be from an inch and a half to three inches in length, and the handle or stem from six to eight inches. Under certain circumstances, the ordinary form of the instrument may be conveniently departed from, in consequence of peculiar conformation of larynx, or where it is intended to operate upon the anterior or posterior wall of the tube; in the former instance, the angle may be more acute, and in the latter more obtuse; otherwise, the necessary depression or elevation of the hand, in order to reach the desired spot, will require the possession of a greater amount of skill.

The best method of managing the tongue, is for the patient to extrude it as far as possible, and then to hold the tip himself between his thumb and forefinger, so as to arrest the involuntary backward movement when an instrument is passed within the mouth, a cloth being interposed between the tip of the tongue and the fingers to prevent its slipping. Patients soon learn to hold the tongue properly and quietly, without grasping it. If it is absolutely necessary to employ a tongue depressor, an instrument should be selected which will reach well back to the base of the tongue, which is then to be forcibly depressed and drawn forwards, and the management of the tongue depressor should be entrusted to the patient. The less paraphernalia employed, however, the better. Tongue depressors, head rests, and laryngeal "*fixateurs*"—instruments attached to the patient's head, or to his jaws, and provided with a fork, which is to hold the laryngeal mirror in position—all produce more or less restraint on the part of the patient or operator, and their use is therefore to be avoided unless imperatively needed, an emergency which is, happily, of rare occurrence. When a patient is unable to maintain his head in a proper position without extraneous support, the best rest for it is the breast of a friend, or that of an assistant, who should place one hand upon the forehead. The writer sometimes employs Tobold's head rest, when an assistant is not within call. If the tongue is very fleshy or very unruly, a depressor may become indispensable. It is difficult to conceive of any case in which an instrument for holding the laryngeal mirror in position can be judiciously employed, for it would become spattered by cough, etc., necessitating frequent readjustment, which would prove exceedingly irksome and vexatious. If the operator require the use of both hands for instrumental purposes, the mirror can be managed by an assistant, or in many cases, and what would be far preferable, by the patient himself, who can often be taught to keep the mirror in position after it has been properly placed by the operator; and indeed some patients have learned by practice during protracted treatment, to introduce the mirror themselves, and place it at once in the desired position.

Light, patient, tongue, etc., being in proper adjustment, the mirror is introduced with the left hand, if the operation is to be performed with the right, or *vice versâ*, and with the other hand the instrument is to be passed well back into the pharynx and close to the mirror, until its point can be clearly discerned in the mirror, and avoiding contact with any of the structures; then, with the image in the laryngeal mirror, as "the guide to the operating hand," the point of the instrument is to be directed towards the desired spot, and, following the reflex, to be carried there promptly and quietly. The instrument should be taken in hand as if it were a pen, not as if it were a cart-whip, as too many are apt to hold it, and the fingers being extended

on the wrist, the laryngeal portion is to be carried over the tongue, until its approach is seen in the mirror. It is not always, even after long practice, that the actual contact of the instrument with the diseased spot can be seen in the mirror, for usually, and perhaps always, at a first application, spasmodic action ensues at the moment of contact; and very often the instrument, if not promptly withdrawn, will be caught by the epiglottis or by the base of the tongue, an occurrence which it is desirable to be able to avoid, although under certain circumstances, as when a general application is being made by means of a moistened sponge, the action may be advantageous, inasmuch as it compresses the sponge, and thereby secures the discharge of its fluid. Under these circumstances, the character of the contact is to be determined by the impression conveyed to the finger by the end of the instrument. As soon as practicable, which is as soon as the spasmodic action induced by the operation ceases, the parts are to be reëxamined in the ordinary manner, in order to judge of the success of the application, as well as to determine the necessity for its repetition in case of failure.

Patients soon become accustomed to the momentary contact of a foreign body against the laryngeal mucous membrane, but at the earlier interviews the distress is often extreme; there is a great deal of spasm, with choking sensation and expectoration, while the sense of constriction and dread of suffocation sometimes remain for several minutes. It is the same as when a foreign body has been removed from the conjunctival mucous membrane, the sensation of its presence remains for some time; and, from a similar cause, patients will "feel the sponge in the throat" after its withdrawal, and this will keep up the feeling of impending suffocation, so that they will sometimes throw themselves from side to side, walk about the room, approach the window to get a breath of air, etc., and occasionally exhibit an amount of distress piteous to witness. With each repetition, however, the sensibility of the parts decreases, until, after a while, the application will be followed by a mere clearing of the throat. In the earlier applications, too, the effect will be to induce active congestion of the parts with increased secretion, which will be followed by a sense of roughness, dryness, or burning, in greater or less degree, continuing from fifteen minutes to several hours. As the applications are repeated, these effects, too, gradually diminish in intensity. The swallowing of cold water will often materially alleviate this distress, when it is severe; and if it continues for some time, the inhalation of an anodyne solution or vapor will overcome the irritation.

Very often a skilful operator can succeed in making a successful application at the first interview with his patient, but with those who are less practised, and in all cases of extreme irritability of structures, a certain amount of preparatory manipulation becomes requisite. The plans recommended in the writer's recent articles on laryngoscopy, *see Vol. I., p.* 359 (to which he may add that the hypodermic injections of anodyne solutions has not produced very satisfactory results), may be employed. The best method is the contact of some extraneous body. I often show a patient how to pass an instrument into his own larynx, a probang with a small sponge attached, for instance, and direct him to moisten a sponge with water, and insert it into the larynx two or three times a day, until the contact of the instrument can be borne without flinching. This practice is necessary at times, preparatory to the employment of cutting instruments; less so when cauterization or general applications are to be instituted. Very often the epiglottis is more irritable than the interior of the larynx, and to overcome this the best plan is for the operator to pass his finger behind the patient's epiglottis, and pull it forward several times, and then to teach the patient how to perform the manœuvre himself, and direct him to repeat it occasionally at intervals during the day. Then he may be provided with an extension thimble, with a good, broad, blunt end, and insert that several times a day. When the epiglottis is very much depressed, the patient must pull it forward frequently, so as to induce it to assume a more erect position. A patient can be taught to raise the epiglottis with one fore-finger, and then to pass a sponge probang along the back of the finger down into the larynx. By this, or some similar method, the sensibility of the part will be gradually subdued, and it is surprising sometimes how soon the irritability is overcome. And here we are led to an important practical observation, which is, that a patient who has been suffering a long time with severe disease, even when of nervous temperament, will learn to control his sensations promptly, while one whose trouble is trivial or imaginary, will require longer tuition and preliminary manipulation. Again, it will be noticed, that a patient who may be exceedingly docile, and may coöperate well with his physician during the earlier interviews, will sometimes become less tolerant of manipulation as relief is being obtained.

Where obstinate depression of the epiglottis precludes the convenient introduction of an instrument, it will have to be forcibly raised by means of properly curved forceps, hooks, or pincettes, of which that of Von-Bruns (*described at page* 349, *Vol. I., of* THE MEDICAL RECORD) is the best.

Certain precautions are necessary to success in limiting a local application to certain portions of structures, and in order to gain access to others; and for this purpose we avail ourselves of the physiological effect of voluntary movement. Thus, if we want to medicate the floor of the glottis, or prevent any of the material used from entering the trachea and lower laryngeal cavity, we direct the patient to emit a vocal sound, which of course closes the glottis; if, on the contrary, we desire the instrument to enter the lower laryngeal cavity, or penetrate into the trachea, we direct a deep inspiration to be taken which opens the glottis and permits the passage of the instrument between its lips; if we wish to make an application to the laryngeal surface of the epiglottis, or to the anterior portion of the vocal cords, ventricular bands, etc, we direct the forcible extension of the tongue, and the utterance of a high note or an ironical laugh, in order to expose these structures more fully; if we wish to touch a spot upon the lingual face of the epiglottis, or in the glotto-epiglottic sinuses, or upon the base of the tongue, we allow the base of the tongue to remain in a more natural position, or cause it to be protruded in such a way as will not raise the epiglottis to its erect position, etc. Then, again, the preliminary movements of retching, swallowing, coughing, etc., will raise the entire larynx, and bring the structures within nearer reach of an instrument.

With these general remarks, we are able to enter upon the special consideration of our subject.

AGASSIZ AND AMERICAN ARCHÆOLOGY.—It is rumored that Professor Agassiz and the senior class of Harvard University contemplate a visit to southern Ohio, for the purpose of a scientific investigation of the antiquities—tumuli, fortifications, and other remains—of an extinct race, in which it so greatly abounds.

CONSUMPTION OF CONFECTIONERY IN PARIS.—According to the Parisian Chamber of Commerce about eleven millions of francs were spent in bonbons last year.

ANAPHRODISIA.

TRANSLATED FROM THE FRENCH OF M. AMBROISE TARDIEN DE L'HOPITAL LA ROBOISIÈRE, PARIS.

By WM. MASON TURNER, M.D.

PHILADELPHIA.

The name *Anaphrodisia* has been given to the inertia of the genital organs, and to the enervation or the abolition of the genital functions.

It is not necessary to confound anaphrodisia with impotence (*agénésie*) and sterility (*aphorie*), which in men and women indicate a total impossibility of the perfect accomplishment of the generative act, and the reproduction of the species. Anaphrodisia is simply one of the forms—one of the sub-divisions of impotence. This can, in fact, depend as well on a mechanical difficulty in the emission of the sperm, or on a defective ejaculation; and in women, on a faulty organic conformation, or on a menstrual derangement, as on an irritable nervous atony, and on a deficiency in the generative power.

Anaphrodisia in man is ordinarily characterized by its slowness, defect in energy, and later by the absolute impossibility of erection of the penis, accompanied in the beginning by premature emissions, which are provoked by the slightest attempt at coitus. The spermatic secretion, and oftener still the venereal desires and exhilarations which are its prelude, gradually diminish, and finally become null. Among females, anaphrodisia is infinitely more rare, and is very difficult to determine, on account of a somewhat passive *rôle* to which the sex is often reduced. For the rest, it consists in a particular insensibility, a veritable atony of the genital organs, and an absence, more or less complete, of the *needs* and *pleasures* of animal love.

Anaphrodisia affords a great number of varieties, in regard to its march and the causes which produce it. Without referring to that which results physiologically from increasing age, and which can otherwise be retarded or advanced by special circumstances inherent to the constitution, anaphrodisia can be in some degree *congenital*, and dependent upon an original constitutional vice. Subjects who are infected, have generally a peculiar physiognomy. Their natures are effeminate, lymphatic; their forms rounded, sometimes amounting to *embonpoint;* the capillary system is meagre, or wholly wanting, especially in the neighborhood of the sexual organs; the voice is shrill and piercing, the genitals are but slightly developed, resembling atrophy; in women the breasts are scarcely formed, and the menstrual flux scanty; the character, apathetic and without energy.

In other cases, anaphrodisia is *acquired* and prematurely determined by venereal excesses commenced before age, and which have early enfeebled the generative system and the entire constitution by onanism. Sometimes, on the contrary, by an absolute abstinence, and a default in the rightful use of the genital organs, or again by an excessive and habitual tension of mind by exclusive pre-occupations, which lead in their train to ideas of ambition, to speculations in money, and to devotion to science.

Finally, anaphrodisia can be simply transient, and be produced by a too great abuse of the pleasures of love, by the enfeebled state which follows a serious illness of long duration, by the accidental and immoderate use of spirituous liquors, drunkenness, and the excesses of the table. It likewise is due to certain moral impressions, which, by a singular contrast, instantaneously paralyze every species of genital power in men. Such are, especially, excessive keenness of desire, timidity, distrust of one's self, and an unforeseen distraction in the act of coitus.

That which we have spoken applies exclusively to *essential* anaphrodisia; and we ought to add that this affection is often nothing more than a *symptom* which is observed at the beginning of brain derangements, in diseases of the spinal marrow, and in paraplegias, of which it is one of the first and best premonitory signs. It is met with likewise in diabetes, in different cachexias, in severe leucorrhœas, in certain rebellious gastralgias, and in asphyxia from the fumes of charcoal, after each of which it lasts for a certain time.

The treatment of anaphrodisia is necessarily subordinated to the different causes which we have enumerated. If it be often beyond the resources of our art, as when, for example, it is congenital, or when indicated by an anticipated old age, it is not always the same, in cases where the atony of the genital organs is recent, or where the disease is attributable to a cause which can be efficaciously combated. A tonic regimen, cold affusions, lotions, or douches followed by frictions on the vertebral column, on the organs themselves; and sulphuretted mineral waters, are the means which guarantee most success. It is best likewise to add the preparations of nux vomica, the action of which (continued with prudence) produces often the most brilliant results (*Trousseau*). We must count less on cantharides, phosphorus, and the numerous aphrodisiac remedies, which are so dangerous, and generally so little to be relied on, that their employment cannot be sustained.

Original Lectures.

EXTIRPATION OF THE UTERUS BY MISTAKE FOR OVARIAN TUMOR:

BEING REMARKS MADE UPON THE PRESENTATION OF THE SPECIMEN TO THE N. Y. PATHOLOGICAL SOCIETY, JUNE 27, 1867.

By E. KRACKOWIZER, M.D.

Mr. President—This is the body of a uterus, in the walls of which is imbedded a large fibroma, which was removed by mistake for an ovarian tumor; at least I ought to say that I only became aware that it was a uterine tumor when it was too late to arrest the operation.

The woman from whom it was taken was forty-eight years of age. She had been delivered when she was twenty years of age of a healthy child, and from that time she menstruated regularly. She did not marry, however, until she was thirty-five years old, and was without issue for four years, when her husband died of consumption. She remained a widow three years, and married again eight years ago, no children, however, being born. She was always in most excellent health, and menstruated regularly up to the time of the operation. About two years ago she felt that her health began to get somewhat impaired; she could not describe in what manner, save that she did not have her previous vigor and activity, and that her appetite became impaired, and that it seemed to her more difficult to attend to the duties of her household than heretofore. One year ago a swelling in the lower part of the abdomen appeared; it did not increase, however, to any considerable degree, or with any marked rapidity, and its presence only occasioned her uneasiness.

I saw her for the first time about six weeks ago, and made an examination into her case. The tumor, which was about the size of a child's head two years old, was

felt occupying the lower part of the abdomen. It was smooth, elastic, painless on pressure, and movable from side to side. On making a vaginal examination, it was found that the mass bore down behind the symphysis pubis, and had crowded the uterus backward. The os was felt on the posterior part of the tumor. A uterine sound entered with great facility to the depth of two inches and a half behind the tumor. When the sound was grasped by one hand and the tumor held with the other, it seemed to move independently; I therefore concluded that I had a simple ovarian tumor to deal with, and that the uterus was normal and unconnected with it. I supposed that the pedicle was a pretty short one. No examination per rectum was made.

The condition of things was explained to the woman. After stating to her the chances which she had if the tumor were left alone, or if the operation were undertaken, and after sufficient time had been given her for deliberation, she most decidedly preferred to have a radical operation undertaken. I then called in Dr. Kammerer, to get his advice in the matter. He made an examination, and corroborated my opinion in every respect, except that he thought that the tumor originated from the left side, while I was of the opinion that it came from the right side.

The day before yesterday the operation was made. After chloroform was administered, an incision was made midway between the umbilicus and symphysis pubis to the extent of four inches, and the tumor was presented. I must state that at the previous examinations, never having felt any fluctuation, I was of the opinion that the walls of the cyst were very thick. When the peritoneal cavity was opened sufficiently wide so as to introduce the hand, it was found that the omentum was adherent in several spots on the surface of the tumor. On the left side a band was detected, with a somewhat cylindrical yielding mass in it, which seemed to be the dilated Fallopian tube of the left side. On bringing the hand between the promontory and the tumor, the mass was found to be connected most intimately with the cervix uteri. Before that was done, however, a trocar was plunged into the mass, and on introducing the trocar I became aware that I had to deal with a solid tumor, as no fluid escaped and the end of the trocar was firmly held fast. A great deal of venous oozing took place from this spot. Between the promontory of the sacrum and posterior aspect of the tumor I could feel plainly the left ovary, and I could also ascertain that the mass was a continuation of the cervix uteri. The uterine sound was passed to the depth of two inches and a half; it was also evident that the tumor was springing from the lower portion of the body of the uterus, which a little above the inner os was swelling out rapidly into a globular tumor.

The question then arose, whether it was better to desist from the operation or go on. In rapidly canvassing the chances which this poor woman had, and which were very slim indeed, it was thought best to proceed. Inasmuch as the tumor had been wounded and hæmorrhage had occurred, the risk of peritonitis was very great; and, further, if it were possible that peritonitis would not follow, the wound itself would give her no more chance if the mass were allowed to remain than if it were taken away. I therefore determined to remove the whole mass. I ligated both Fallopian tubes, and of course part of the broad ligament, and after the ligation of these bands, and when the tumor became more movable, I lifted it out of the abdominal cavity, pulling it well up above the symphysis pubis, so that the neck of the tumor could be seen and felt. I then carried the chain of the écraseur around it, and proceeded very slowly to close it. I was fully three-quarters of an hour in accomplishing this, in the fear that by proceeding more rapidly hæmorrhage might ensue. After the chain had worked through the rest of the womb, that is, the cervix being still upon the stretch above the symphysis, no hæmorrhage was visible, but as soon as the stump was fairly liberated the whole field of the operation was deluged with blood. The stump was again grasped with the forceps, and both uterine arteries were secured, but the uterine veins, as well as several sinuses in the cervix itself, continued to pour forth blood, and these with great difficulty were at length secured. For greater security against accident, a silver wire was then twisted around the end of the stump, and the ends brought out of the wound.

The loss of blood was considerable, but the pulse did not indicate an anæmic condition of the body.

The operation took fully two hours and a half. The wound was closed with five silver-wire sutures. A hypodermic injection of Magendie's solution was then administered, and, as the result, she slept quietly an hour, after which she awoke. I saw her about seven o'clock in the evening, and she was then in a tolerably comfortable condition. There was, however, a good deal of tenderness on the right side of the umbilicus on the slightest touch, otherwise the abdomen was not tender. Four drops of Magendie's solution were given every hour during the night. After midnight she became restless and commenced to vomit. She vomited several times after I saw her next morning, about seven o'clock. It was then very evident that peritonitis was extending rapidly. I made a hypodermic injection again, and during my absence large doses of Magendie were given. About one o'clock in the afternoon she was in a sinking condition, there being no pulse at the wrists, and at four o'clock she died.

No post-mortem examination was made, and I do not believe that had it been done much more light would have been thrown on the case, so short a period of time having elapsed from the operation to the death.

On introducing a catheter or sound into the cavity of the womb, it will be seen that the uterine canal reaches up a good deal higher than at the original examination. If I had not had my mind preoccupied with the existence of an ovarian tumor, and if, on account of some obstacle, the probe had not been arrested at just the depth of two and a half inches, I should have been prevented from making this deplorable mistake. I suppose that the sound was arrested by some projection into the cavity of the uterus, and possibly I did not make effort enough to get it beyond that point.

The specimen has been incised by a longitudinal cut, and it will be seen that a large fibroma is embedded in the walls of the uterus, and that this mass has nothing to do with the cavity itself.

I must mention that in the progress of the operation, when the chain of the écraseur was tightened, the centre of the mass seemed to be occupied by a hard, irregular mass, and that there was a looseness of the investing walls noticeable. In a similar case, if I should be caught in such a tight place, I would from such a symptom be led to modify the operation; that is, instead of removing the uterus, and giving the patient an almost infinitesimal chance, I would incise the walls of the tumor and enucleate the mass. Hæmorrhage would have occurred, but it would not have been difficult to secure the bleeding points as they in turn showed themselves. A very loose pouch would, of course, remain, but that to a great extent could be resected, and the edges in apposition secured by sutures. The mistake that I made in supposing that the tumor

was movable independently from the uterus is explained by the fact that the womb, just at a distance of two and a half inches from the os externum expanding rapidly to a globular mass, would rock from one side to the other when moved by the hands through the abdominal walls, as it were, on the extremity of the uterine sound introduced to the depth of normal length of a healthy uterus without imparting this motion to the sound itself.

Progress of Medical Science.

ERGOT IN SPOTTED FEVER.—A well-marked case of cerebro-spinal meningitis, which resulted in complete recovery, after running a course of 164 days, is reported in the *Boston Medical and Surgical Journal*, July 18th, 1867, in the treatment of which ergot seemed to have more influence in controlling the symptoms directly referred to the nervous centres than any other remedy employed. The wine was used in doses ranging from 20 to 40 minims three or four times daily.

EXTIRPATION OF NAIL OF THUMB UNDER ANÆSTHESIA BY COLD.—Dr. John Parsons, of Mt. Pleasant, Kansas, reports the following case in which local anæsthesia was produced by the mixture of snow and salt:

"Mrs. B., who had been treated by charlatans with salves, etc., for the past four months, without any benefit, lately applied for treatment, and I decided to remove the partly detached nail of the right thumb. As she dreaded the pain of the operation, and also taking chloroform and ether, I concluded to try *freezing* with snow and salt. In two minutes, the thumb being insensible to pain, I quickly extirpated the nail. The thumb was then thawed in water, and then simply dressed. Seven days after the operation it was healing rapidly, and a new nail had appeared."—*Am. Jour. Med. Sciences.*

BROMIDE OF POTASSIUM IN PUERPERAL CONVULSIONS.—The following interesting case is reported in the *Am. Journal of Med. Sciences*, by Dr. Chas. C. Shoyer, of Leavenworth, Kansas. He thinks it the first in which the bromide of potassium has been used in the treatment of puerperal convulsions, and asks that the drug may have a further trial.

Mrs. H., aged 18, primipara, was seized April 30th, with a severe gastric pain, which Dr. S. at his first visit thought was caused by the inception of labor; at a second visit, however, the true seat was recognized, and it was easily controlled by small doses of morphia with co. spts. lavender. During the night she vomited and had two stools from a half ounce of ol. ricini; she had a craving appetite, and ate largely of meat, bread, etc., swallowing without mastication, as the event proved; this continued throughout the night, and in the morning of May 1st, she got up at 7 A.M., for the purpose of eating again, but fell to the floor fainting; upon being placed in bed she had a series of violent convulsions. When seen at eight o'clock she was strongly convulsed, breathing stertorously, pupils insensible to light, teeth firmly fixed, and frothing at the mouth.

Five drops of ol. tiglii were given in the course of an hour without any effect. Chloroform was found to quiet the convulsions only during its administration. Dr. S. having ascertained that the child was dead, now punctured the membranes, with a view to inducing labor. In a short time she began to vomit, throwing up large pieces of bread, meat, and other food. She now became quiet for a short time, during which a purgative mixture was exhibited, which was followed by three copious evacuations, voided in the bed, the patient being unconscious. After this she was quiet for nearly three hours, but the pains of labor setting in about 5 P.M., she had several convulsions in rapid succession. Upon consultation it was determined to give the bromide of potassium in fifteen grain doses hourly, and to be governed by its effects. From the time of its first administration to the end of labor, a period of 21½ hours, she did not have another convulsion. The bromide was given five hours successively, and then at greater intervals, as the stertor had ceased, and she was somnolent; towards the end of labor the intervals were four hours.

The child was born at 2½ P.M. of the 2d, was about 8½ months old, and had been some days dead, as the epidermis was peeling. She took in all 2½ drachms of bromide during 19½ hours. She remained somnolent until the morning of the 3d, and then awakened as from a prolonged slumber, having no recollection of the past, not even that she had given birth to a child. A specimen of urine was examined 30 hours after confinement, and found free from albumen.

THE OPHTHALMOSCOPE AND THE PHYSICIAN.—Dr. J. V. Solomon, of Birmingham, in a late issue of the *British Medical Journal*, makes the following remarks:

I find all impediment to focussing of the fundus to be at once overcome if the student suspend the power of accommodation of his right eye by the application of a four-grain solution of atropia (*British Pharmacopœia*) half an hour before making his ophthalmoscopic examination.

This being done, and the iris of the patient fully dilated, he has only, after having observed the usual rules laid down in ophthalmic works, to gently move his head a little backward or forward, as the case may be, and a complete picture of the optic nerve and its surroundings starts into view.

The physician will do well to select a case of extreme short sight, atrophy of the optic nerve, or a light blue normal eye, for his first experiment, and continue his observations every day. By the time the action of the atropia has subsided, he will, if endowed with good vision and some manual tact, find himself master of a step in ophthalmic investigation which had hitherto been considered by him as insurmountable.

UNUSUALLY RAPID ACTION OF THE HEART.—Dr. Richard Payne Cotton reports a case in the *British Medical Journal* of unusual rapidity in the heart's action. The patient was a tailor, 42 years of age, who from time to time had been subject to paroxysms of palpitation. These were in each case preceded by loss of appetite, acidity, and disordered stomach, with constipation, the rapid action of the heart following immediately upon a sensation of faintness and short breathing. When called to see the patient in one of these attacks, the physician found him anxious, but not otherwise seriously distressed; his breathing was short, hurried, and irregular, varying from thirty to forty in a minute. The pulse was too rapid to be depended on; but the beating of the heart was distinct, regular, free from murmur, and *two hundred and thirty-two* per minute. Immediately over the semilunar valves both sounds could be clearly distinguished, scarcely differing from each other, and closely resembling the peculiar "tic-tac" beats of the fœtal heart; but in every other part of the cardiac region a single and abrupt sound only could be heard. No valvular murmur could anywhere be detected, neither was there any visible pulsation in any of the larger arteries; but the jugular veins, as well as the larger veins at the bend of the arms, could be distinctly seen to pulsate. Subsequently the sphygmograph was employed, and the tracings, which were remarkably regular, representing mere ripples, proved the pulsations at that time to equal 220 per minute. The

attack passed off, as did all previous ones, suddenly. The treatment consisted first in the use of antacids and stimulants, during the action of which a considerable quantity of tape-worm was expelled. After a short time the tincture of digitalis was given in doses from 10 to 15 minims three times a day; and it was during the use of this medicine that the heart returned to its normal pulsation—that of 70 per minute. Notwithstanding the immense rapidity of the action of the heart during the paroxysms, the patient was not considered at any time in danger. In conclusion the reporter remarks:—"In the case before us, either one of two conditions may have existed. The presence of the tape-worm may have produced a reflex irritation of the heart itself; or the acidity and dyspepsia under which the patient invariably suffered at the period of his attacks may, by giving rise to an abnormal condition of the blood, have provoked the heart to its rapid and premature contractions; and it is even possible that these two conditions may have coexisted. I will not, however, insist upon such an explanation; but, in the absence of even the slightest indication of brain or spinal affection, or indeed, of any unusual amount of general nervous sensibility in our patient, I am at a loss for any other."

Aids to Digestion.—Dr. Marcet, in a pamphlet "*On a new process for preparing meat for weak stomachs*," recommends the use of hydrochloric acid and pepsin as solvents for the cooked flesh previous to being taken for food. He is of the opinion that by this means many irritable stomachs could be enabled to dispose of a certain amount of animal food which under other circumstances could not be digested at all. He gives careful directions for preparing the food.

Phenic Acid for Caries.—Phenic acid is strongly recommended in dental caries by two French dentists, MM. Prest and Victor. They assert that they can obtain a cure in nine cases out of ten, without resorting to extraction.

Action of Sulphuretted Hydrogen on the Blood.—Herren Kauffmann and Rosenthal confirm the observations on the action of sulphuretted hydrogen gas upon the blood, already made by Herr Hoppe Segler. They say that the toxication of sulphuretted hydrogen is simply asphyxia. In cases of poisoning by this gas, the treatment is to introduce oxygen into the blood by artificial respiration, and there is hope of recovery as long as the heart acts.—*Archiv für Anatomie.*

Cervical Ribs.—L. Stieda, of Dorpat, describes the case of a woman, aged 30, in whom a pair of cervical ribs sprang from the seventh cervical vertebra. Except that the left cervical rib was ossified to its vertebra, whilst the right was articulated to it by a movable joint, both ribs closely resembled each other. In each a head, neck, tubercle, and body were found; the anterior end of the body was pointed and connected by a ligament to a plate of cartilage attached to the anterior end of the first thoracic rib. The subclavian arteries had been removed, so that Stieda could not determine their relations. The thoracic vertebræ and ribs, and the lumbar vertebræ, were normal in number. The paper concludes with a brief historical account of the cases previously recorded.—*Virchow's Archives*, 1866, *and British Med. Jour.*

Broadbent's Treatment of Cancer by the Injection of Acetic Acid.—Recent trials of the method of Dr. Broadbent in the treatment of cancerous tumors by the injection into their substance of acetic acid, in the Cancer Hospital, have resulted negatively. The tumors, instead of shrivelling in size, have been found to enlarge, and to take an inflammatory action. In one or two instances in which the method has been employed in this city the same unpleasant effects ensued.

Opium in Therapeutics.—The practice of physicians in America and in Great Britain, if not elsewhere, has changed very much in regard to the use of opium in fevers and some other forms of disease, within the last twenty or thirty years. Some remarks of Dr. Allbutt on this subject, in *Ranking's Abstract*, referring to the use of this remedy in the Leeds (Eng.) Fever Hospital, so entirely accord with the results of our own experience, that we take the liberty of commending them to such of our readers as may still entertain something of the old prejudice: "One year ago," says Dr. Allbutt, "I looked upon opium in fever with much suspicion, granting its occasional value alone, and greatly restricting its use. Gradually my fear of the restlessness overpowered my fear of the opium, and I have now ceased to regard the latter with any great apprehension. Continually I have witnessed the terrible havoc which a night's tossing makes in a little reserve of strength. Two such nights reduce it to a most precarious level, and few patients outlive three. On the other hand, though I and my assistants have been for six months giving morphia at all stages of the fever to combat sleeplessness, I have never yet seen mischief result. I have never seen the power of taking food suspended by it, or the oppression increased. On the contrary, I have continually seen with pleasure how, on the morning after opium has brought sleep, even during the first few days of the disease, the tongue has become moister, the headache less, and the countenance more open. The sleep of an opiate is better than no sleep. Camphor is also a great favorite of ours. We find, on the whole, that no medicine equals it in the low delirium often connected with feeble heart. We combine it with opium in low delirium accompanied with sleeples-ness. Perhaps, however, the most striking in its immediate effects, of all the medicines which we have used, is that which we familiarly call *Graves' Medicine*. The combination of antimony and opium in the wild delirium of fever is advised by Graves in a well-known passage of the *Clinical Medicine*, and a marvellous one it is. Half a grain of morphia, with one-third or half a grain of tartar emetic, with repetition of half the dose if necessary, will bring quietness and sleep to a patient who, an hour or two before, was a raging maniac." We do not exactly agree with Dr. A. that the power of taking food is never suspended by the remedy. But this is a small matter. The distinction between the grades of delirium is important, the combination with camphor being adapted to the low form, and the antimony to the wild and sthenic form.—*Pacific Med. and Surg. Journal.*

Beef Curing by Venous Injection is practised by a firm at Corpus Christi, Texas, according to report, with perfect success. The blood is withdrawn by tapping the right ventricle of the heart, the animal having been stunned; after which the veins are forcibly injected with brine, through a hose, the nozzle of which is tightly inserted in an orifice in the left ventricle, while the orifice in the right ventricle is closed. After filling, the right ventricle is opened, and allowed, under a continued pressure of brine, to run clear of the remaining blood. On making an incision at any point in the carcass, the brine spirts out the same as blood from the living animal, only with greater force. Even the hide is perfectly salted, and the carcass can be kept or transported whole as it stands, or skinned, cut up, and packed, with perfect safety from decomposition.—*St. Louis Med. Reporter.*

THE MEDICAL RECORD.

THE TRUE NOBILITY OF THE MEDICAL PROFESSION.

A DISTINGUISHED professor once said, that "if all the medicine in the world (with a few exceptions) were cast into the sea, it would be the better for mankind and the worse for the fishes." His other utterances also on matters pertaining to medical practice, sparkling though they be with wit and brilliant with antithesis, can hardly be said to be orthodox, for having thus frequently made out his brethren as fools or hypocrites, our autocrat says that he has looked in vain for a wicked physician to serve as a character in a story. Here again we should be glad if in our kaleidoscopic view of the great and good among us, there were not obtruded the dark shapeless bodies of those who dishonor us by evil practices, covered up with the usual cant about the nobility of the profession. This cant is, indeed, a very common thing with us. If we were to believe the words of physicians themselves, as uttered in valedictory addresses, obituary notices, editorials in medical journals, our profession ennobles all upon whom its mantle falls. That there may be an intrinsic nobility in our calling, we are ready to admit; yet the nobility consists not so much in the nature of the work among the sick and suffering, as in the manner in which that work is done. There are some aspects of our profession in which it is a trade, and an honest one too, entitled to all the respect given a skilful and honest worker in any chosen calling, but no more. For instance, all-night attendance upon a very sick patient, with a handsome fee looming up in the future, may or may not be a philanthropic act, only so far as the actuating principle be founded on a correct motive. In other words, much depends on the spirit with which the work is done. Mutual admiration on the part of physicians, it seems to us, is a little overdone. We are not accustomed to hear the men of other professions indiscriminately laud their calling. Since we have voluntarily chosen our work, this laudation of the profession by implication praises us. As after all we get our living, in most instances, by it, and avowedly practise it for money, this sort of excessive talk about philanthropy seems in doubtful taste. Let us set about to reform the profession. Let us discountenance the evil practices, which in so many instances spring from their toleration, by those who should be the very ones to exemplify the nobility of the profession of medicine.

"A stream cannot rise higher than its fountain," and until our medical schools make some inquiries as to the moral and mental qualifications of the candidates for matriculation and graduation, the medical profession will be far from being in that fanciful condition which cannot furnish a wicked character for a novel. As we have often said in these columns, impliedly at all events, there is no qualification now required to enter a medical college, except the pecuniary ability to pay one hundred and forty dollars per annum. On graduating, no questions whatever need be *legally* asked, except "have you paid for your tickets, studied three years, and passed your examination?" As a result of this beautiful and noble system, is it any wonder that some men who graduate at respectable colleges, immediately rush into all sorts of deluding practices, among which that of homœopathy may be mentioned? In such a condition of the market—where the demand for character, much less for reputation, is so slight, can we complain that the supply is in proportion? We intend never to leave this subject, until reform has begun at the head of our profession—until medical schools cease to display so largely the money-making object, which, in the end, cannot but tend, by the number of unworthy ones admitted to our ranks, to lower so materially that high standard of excellence for which we are all naturally eager. While therefore, we may be reminded that "it is an evil bird which fouls its own nest," at the same time, without even challenging for admiration the acts of the truly noble men in the profession, we may be consoled with the reflection that the memory of the great army of Esculapian soldiers, whose names shall ever be honored so long as science has its votaries or truth its disciples, presents themes broad and ample enough in scope, for the most craving eulogist. Let us ask then, in view of the indiscriminate laudation which is heaped upon our calling by medical men themselves, how can we do otherwise than raise the notes of warning, lest our junior practitioners hug the delusive idea that an entrance into the profession has of itself ennobled them.

Individual self-sacrificing work, not alone for a living, but for the luxury of doing good, done in the same spirit for both rich and poor, and purity of life and heart, —these will ennoble us. But when we practise in this way, let us leave our encomiums to others.

THE organization of a medico-legal society in this city is a feature worthy of notice. Its members belong to the medical and legal professions, and its object is the discussion of all matters pertaining to forensic medicine. That the workings of such a society cannot

but be productive of benefit to both parties, no one can doubt. A vast loss of time in court, an amicable instead of the usual rancorous feeling between the lawyer and his medical witness, and the elimination of many practical truths, must result from a free discussion between the gentlemen of the two professions on a proper subject of inquiry. The plan of the society embraces the selection and discussion of a certain subject at each meeting.

As one great source of knowledge in legal medicine is from the examination of dead bodies, it further provides that every medical member shall use his best efforts to increase the practice, in his profession, of making such examinations, and stand pledged at all times to conduct an autopsy for any physician who may request such service. A report to the society is required from the member making such an examination, and, if possible, its illustration by diseased or injured parts taken from the body.

We should be glad to hear of similar organizations elsewhere.

The new Quarantine Station at West Bank, in the Lower Bay, has not reached that state of forwardness, which, when the contract was awarded, the public had a right to expect. It will be remembered that the works were to cover an area of about two acres, and were to be constructed of solid hewn timber bound in a species of net or lattice-work, and that these cribs were to rise some eight or ten feet above high-water mark. The two cribs now in position have withstood the unusually violent winds and seas of last winter and spring, and are thought by experts, proof against tests still more severe. Mr. Swift has, however, failed in making the requisite progress within the time specified in his contract, since the superincumbent structure is not yet *all* above high-water mark, and until such be the case, the Commissioners of Quarantine decline to pay down any instalments in liquidation of expenses thus far incurred.

We would call the attention of those of our brethren who may be interested in the progress of pharmacy to the coming meeting of the American Pharmaceutical Association in the University Building, on the 10th instant.

We have every reason to believe that the matters to be discussed will be of paramount interest, not only to the pharmaceutist but to the medical practitioner. A new feature will be introduced in the shape of "an exhibition of objects relating to pharmacy," which will be open for inspection for four days, dating from the opening of the session. For the sake of utilization the Association have adopted a programme, which calls for the following articles:

(1.) Chemical apparatus, including those for pharmaceutical processes. This includes apparatus and utensils for evaporation, distillation, percolation, filtration, etc., and analytical apparatus of all kinds.

(2.) Microscopes, microscopical apparatus and objects.

(3.) Apparatus used for remedial purposes, as galvanic and electro-magnetic machines, enemas, surgical appliances, etc.

(4.) Glassware, adapted for the wants of the apothecary.

(5.) Scales and weights, for chemical and store purposes.

(6.) India-rubber goods, for pharmaceutical, chemical, or remedial purposes.

(7.) Improved dispensing appliances, as bottles, boxes for pills and powders, labels, protection against mistakes by pharmaceutist or patient, etc.

(8.) Medicines newly introduced or proposed for use.

(9.) Mineral waters and apparatus, including natural and artificial medicinal waters, and apparatus for making and dispensing them.

(10.) Specimens of chemicals, drugs, pharmaceutical preparations, as also botanical specimens.

(11.) Illustrations of adulterations, and the means of detecting them.

(12.) Improved dietetic preparations.

(13.) Books relating to pharmacy or collateral sciences.

(14.) Historical relics having an interest in connection with pharmacy or its cultivators, as portraits, photographs, autographs, etc.

(15.) Any improvements in branches connected with pharmacy, not included in above.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 24, 1867.

(Continued from page 284.)

GANGRENE OF LEG BY EMBOLUS, AMPUTATION ETC.

Dr. Sands presented an amputated leg on behalf of his colleague, Dr. Gouley. He gave the following description of the case.

A consultation was held yesterday afternoon at Bellevue Hospital upon the case of a woman who was 71 years of age, and who had been in the hospital about five weeks. A very few points in the history of her case were ascertained by the House Surgeon; and it appears that just about seven weeks ago, she, then being in what she considered good health, was seized with a violent pain in the calf of the left leg. This pain extended down the leg, and continued with considerable severity for several days. On the third day following this attack of pain, a dark colored spot was noticed on the top of the foot, just below the instep. At that time, according to her statement, the toes were not discolored; the discoloration, however, spread with some rapidity towards the toes, until all of them were implicated, and also extended very gradually over the ankle and up the leg; and it was only ten days ago that the mortification ceased to extend, and that a line of demarcation became apparent. This line of demarcation was nearly circular about the limb, and was situated about four inches below the line of the knee-joint. It was suspected that this woman labored under heart disease, and the attending surgeon, Dr. Gouley, thought that he had satisfied himself that there was some disease of the aortic valves. His observation was not verified, however, by any of the gentlemen who examined this patient in consultation.

The question arose as to the propriety of an operation, and also as to the cause of this mortification, which it was thought did not exactly correspond with

the description of gangrena senilis. The opinion was pretty generally expressed that the mortification might depend upon the presence of a plug in the principal vessel of the leg, and the reason why this opinion was expressed was that the disease began of a sudden. In regard to the operation, we were not entirely agreed, but the preponderating opinion being in favor of immediate amputation, it was performed by Dr. Gouley. The operation was performed through the knee-joint. The knife was swept around the leg below the joint, making an ordinary circular flap, and I was quite surprised to see how well the stump was covered.

After the removal of the limb, the most interesting part of the specimen centred itself in the examination of the vessels. A very curious phenomenon was noticed at the time of the operation, as no vessel bled sufficiently to require the ligature. The popliteal artery and vein stood out prominently, and were seen to be filled with a recent dark red coagulum. Other vessels were seen plugged in the same way. Dr. Gouley has examined the specimen somewhat hastily. The vessels were, as I have said, plugged at the level of the section made by the amputation, the proof of which is seen in the presence of plugs in the distal extremities of these vessels. This coagulum, in the case of the artery, extends down it for about an inch and a half; and there, just at about the point where the popliteal should bifurcate, the artery is very much distended, apparently by the presence of a globular plug of fibrine of a yellowish-red color, distinguishing it in color from the dark red coagulum which occupies the vessel above. The arterial coats, so far as I can judge by superficial examination, are diseased; they contain patches of atheroma, and appear to be somewhat ossified. Where the embolus is found, all the arteries above the occlusion are healthy, and for several inches below the arteries are pervious, and do not contain coagula. This plug is pretty closely adherent to the inner surface of the popliteal artery.

Now it struck me as possible that this might not be an embolus from another part, but a coagulation in the distended aneurism of the artery. I think that the argument against it is that the color is different. I should, after all, regard the specimen as one of senile gangrene, caused by the occlusion of the vessel by a clot which has been lodged in that particular locality from some other portion of the body.

Dr. Markoe was inclined to the belief that Dr. Gouley's case was one of obstructive gangrene, from the fact that it commenced so suddenly, not at the toes, but upon the dorsum, and that in less than five weeks the gangrene had spread above the middle of the leg, no line of demarcation having formed, as usual, in the middle of the leg.

Dr. Newman remarked that the result would show whether the diagnosis was right or not; if it were due to embolus the patient would get well, if to senile gangrene the patient would inevitably die. This opinion was afterwards endorsed by Dr. Markoe.

ABNORMAL POSITION OF THE TESTICLE.

Dr. Sands lastly presented a testicle which he had removed under the following circumstances: He was consulted in July last, by a lad, seventeen years of age, with reference to a swelling in the left half of the perineum, which he knew had been there for seven or eight years, and which recently had given him trouble in riding on horseback. The patient was aware of the nature of the swelling, and his mind was much depressed in consequence, and suffering besides from seminal emission, he desired very much to have the part removed. A very slight examination proved that it was due to the presence of the left testicle in the region of the perineum. It lay quite to the left side of the median line, and was just about midway between the posterior margin of the scrotum and the anterior margin of the anus. It had some mobility, and could be moved an inch laterally to the right or left, and two or three inches up towards the inguinal canal; but on ceasing the pressure it would resume its former position. The operation was undertaken in the hope of being able to replace the testicle. The first incision through the perineum penetrated the sac of the tunica vaginalis, and exposed the organ. It was then found that the serous sac was very limited in extent, or rather very narrow, it being just large enough to admit the forefinger, and ran up along the spermatic cord, which was lodged closely in the fold between the scrotum and thigh, and ran up three inches and there terminated. From the circumstances of the case the operation of replacement was considered impracticable, and the organ was accordingly extirpated. The testicle was well developed, being only about one-half of its usual size, and the structure was perfect. The wound healed perfectly, and the seminal emissions ceased.

Dr. Sands remarked that, on consulting authorities, he had found that this particular abnormal position of the testicle was rare. In an article upon the subject in *Todd's Cyclopædia*, it is stated that John Hunter first drew the attention of the profession to the subject, and that he saw two cases. No description of them, however, is given. Later, it is stated in the same article, that two cases came under the observation of Ricord. In one of these the testicle was inflamed as the sequence of gonorrhœa, and he was about to open what he thought to be an abscess, when he discovered it on examination to be a testicle. Two were also stated to have been seen by Vidal (de Cassis). The curious fact was, that they were two brothers, similarly affected. A seventh case has been spoken of in one of the British journals, as having been seen and operated upon by Mr. Partridge. The operation of replacement was first attempted, but failing to do so, the organ was removed. Another case was alluded to in *Holmes' Surgery*, in an article by Mr. Humphrey. He speaks of having seen a testicle, not in the perineum, but in the angle between the thigh and scrotum; and he speaks of it in reference to the question, whether it had traversed the scrotum or not. In that instance he found that the cord passed directly upward. Finally, a case has been noticed by a German surgeon, Zeiss, who, in an attempt to perform lithotomy by the left lateral incision, came across the testicle in that locality, and changed his incision to the opposite side.

The Society then adjourned.

The Embalmed Body of the late Emperor Maximilian.—"In regard to the body of Maximilian," says a *Herald* correspondent, writing from the city of Mexico under date July 29th, ult., "it was embalmed by Dr. Ribadaneira, Medical Inspector of the Army of Northern Mexico, on the staff of General Escobedo. After the embalment it was taken to the chapel of the Convent of the Capuchin Nuns, where it lay a few days ago under a guard awaiting to be claimed by some competent and authorized person. It is stated that the doctor has a claim upon the corpse for $10,000 or $20,000, professional fee for services, and that it is held for this fee. The coffin is an ordinary affair, the face of the corpse covered with glass. The body is poorly dressed, and imperfectly embalmed."

Correspondence.

MEDICAL MATTERS IN PARIS.

(From our own Correspondent.)

To the Editor of the Medical Record.

Sir—At the last *séance* of the Academy of Medicine the discussion on tracheotomy was continued, and M. Peter made quite a discourse on the subject, describing the practical difficulties in the way of the operation, and suggesting means of overcoming them. Among the principal, is the small size of the trachea in young children. The operator is liable, in making an incision with the bistoury directed perpendicularly to the windpipe, to pass completely through that organ to the œsophagus. Again, the index-finger used to hold the trachea in place, frequently pushes it to one side, so that the incision is made to the right or left of the median line. This would be of small consequence if the trachea was steadily maintained in the first position, but too often the finger slips, the trachea returns to the middle of the throat, and the incision is concealed from view. These difficulties are more formidable as the child is younger, but M. Peter thinks that the age alone never offers a formal contra-indication, since it is well in case of need to operate on the smallest child, and give it a chance for life at a moment that all others are lost.

M. Peter considers, however, that tracheotomy is never necessary, and therefore never advisable, except in cases of pseudo-membranous croup, and believing that pseudo-membranous angina invariably accompanies this disease, he abstains from the operation whenever he cannot find false membranes in the pharynx. The extension of the membranes to the bronchial tubes is, however, of course a circumstance of unfavorable omen for the operation. It is often difficult to diagnose this complication. M. Moutard Martin signalizes pale asphyxia as an excellent sign. M. Peter adds, an unusual frequence of the respiratory movements, whose rapidity is slackened in simple laryngeal croup. Whenever there are more than fifty inspirations a minute, there is good reason to suspect a pseudo-membranous bronchitis.

Subsequent to the operation, the practitioner possesses another sign of this formidable complication. When the canula left in the tracheal wound does not become filled with mucosities, when at the end of twelve hours it is still dry, there is too good reason to believe that the mucous surface of the bronchial tubes is covered with false membranes which effectually prevent secretion.

M. Peter declares that pseudo-membranous bronchitis is quite frequent, occurring, in his experience, 52 times in 105 fatal cases.

Pneumonia coincident with the croup does not absolutely forbid the operation. M. Grisolle observes, that his first successful case of tracheotomy was embarrassed by this complication. M. Nelaton had been called upon to operate, but recognizing the concomitant pulmonary lesion, refused. M. Grisolle then assumed all the responsibility, and operated himself—the child recovered.

M. Archambaud had obtained 21 cures among 67 operations, including two upon adults. The most of these cases had already reached the last period when the operation was performed, the patients sometimes being completely insensible. Among 53 operations made under such circumstances, 17 had succeeded, and among 12 cases treated at an earlier stage of the disease, 4 were saved. The proportion therefore is about the same.

M. Peter assumes as contra-indications, an excessive waxy pallor, ganglionic engorgement, extreme puffiness of the neck, which is neither œdema nor emphysema, all signs of general intoxication.

Cases of stridulous laryngitis are successfully treated by M. Peter with steam. The child is surrounded by half-a-dozen basins filled with boiling water, so that the respiratory organs may be incessantly bathed in the humid atmosphere; the croupal symptoms generally subside in about an hour.

The month of June has been unfavorable for the performance of tracheotomy, since out of eight operations, divided equally between the Children's Hospital and Hôpital St. Eugénie, six have proved fatal.

Appreciation of Medical Constitutions.

This observation enters into a report, presented by Mr. Besnier to the Academy of Medicine, on the medical constitution for June. An effort is being made just now to collect materials for a rigorous appreciation of "medical constitutions." The value of such an appreciation cannot be too highly estimated, when it is remembered how largely this condition enters as an element into the effect of medical treatment. There can be no question, that the reputation of a large number of methods and medicines has been made by the fact that they were administered at a moment when the disease had assumed a benign type, and tended of its own accord to a favorable issue. During this month of June, nearly all the cases of typhoid fever in the hospitals have recovered. There has not been less, but rather more of the disease than usual, and the first stages have frequently opened with considerable severity, but any dangerous symptoms have quickly abated, and the course of the malady has been equally satisfactory under any treatment. This reminds me of an amusing anecdote related by Dr. Maximin Legrand in the feuilleton of the *Union Médicale:* One day, the *garçon de service*, employed in the wards of Mr. Fouquier, appeared with two black eyes, and his face covered with bruises. "What is the matter with you, my man?" inquired M. Fouquier, always kind and polite. "I have been fighting with M. Bouillaud's *infirmier*, and he is better done for than I am." "You were very wrong; what were you fighting about?" "Because he insisted that it is always necessary to bleed in typhoid fever!" The gravity of the physician was not proof against this unexpected reply.

When it is remembered that M. Bouillaud is the author of the famous system of bleeding in pneumonia twice a day, *coup sur coup*, and extends his sanguinary propensities to typhoid fever also, the belligerent enthusiasm of his humble subordinate may be easily explained.

The Administration of Mercury in Syphilis.

At the Imperial Society of Surgeons, the discussions still turn upon the question of the administration of mercury in syphilis, a question that seems subject to periodical agitation. The most conspicuous part of the debate has been that sustained by M. Desprès, whose views have been entirely special, "so special," observes Dr. Reveillant, "that he remained entirely alone in his opinion." For M. Desprès is radical enough to deny any efficacy to mercury whatever, in the disease in which it has for so long been considered the sheet-anchor. He is resolved never to administer the baneful drug either in primary, or secondary, or tertiary syphilis. Theoretically, he bases his principles upon the idea, that the malady is already so exhausting to the patient, that the debilitating effects of mercury can work him nothing but injury. Practically M. Desprès appeals to the result of his experience in the Hôpital Leourcine, among 234 patients, of whom some were

subjected to the classical treatment, others to a course of tonics. Among the first, a percentage of 28 for 100 returned after more or less time to the hospital for fresh treatment of the disease, while in the second class the returns were only 10 for a hundred. M. Desprès declares, rather fancifully, that the physician should endeavor to restore his patient to a "life of infancy," regulating his food, sleep, and exercise, building up his shattered constitution, and that nature would eliminate the poison. "We cannot believe that a purely empirical medicine can be a contra-poison against syphilis, or that there is any sense in employing a drug that exists in the blood like foreign matter, which does not assimilate with a single fluid, and which, even in exercising a certain perturbating and deleterious effect on the economy, neither solicits nor suspends the regular exercise of a single function."

The only points of importance in M. Desprès' remarks, are the statistics, and their value is vigorously contested by M. Depaul. He observes that the comparison between the two modes of treatment was not sufficiently extended, and moreover, that the basis of comparison was fallacious, since a number of the patients who had been treated by expectation, probably absented themselves from the clinique, not because they were cured, but because they were disgusted with the treatment. Nothing exasperates a hospital patient so much as the suspicion that nothing is being done for him. He maintained that this expectant system was extremely dangerous, since the most serious destruction of tissue, such as the perforation of the palatine vault, might take place while the physician was watching with folded hands. M. Depaul laid especial stress on the efficacy of mercury administered for syphilis contracted during pregnancy, when, he declares, it *uniformly* prevents abortion, in recent cases.

A case that recently occurred in the service of M. Hérard at Laribaissière, which I had an opportunity of observing myself, is in entire accordance with this assertion. The subject was a woman of about 35, in the third month of pregnancy. Several years previous she had been treated at Lourcine for primary syphilis, and two years ago had been an inmate of Laribaissière for syphilitic angina. Each time she had completely recovered, and it was impossible to ascertain whether the renewal of the disease was a manifestation of the original malady, or the result of a new infection. At the moment of her entrance, in June, the patient presented an eruption of syphilitic erythema, copper-colored blotches disseminated over the entire body; a small tumor on the right frontal bosse, with broad base, but slight elevation, but the seat of lancinating pains exasperated at night, and which extended also to the temples and the ears: a gray ulcerated fissure at the left commissure of the lips; a grayish *plaque muqueux* on the right labium majus of the vulva. Fine subcrepitant râles could be heard at the summit of the left lung. A cough had existed for several months, but the patient professed to have been perfectly free from syphilitic accidents at the commencement of her pregnancy. She was ordered a pill of corrosive sublimate containing five centigrammes, to be taken every evening. This was the 11th of June. On the 12th, in addition she commenced to take 25 centigrammes of iodide of potassium every morning. By the 19th the pains in the head had entirely ceased, and the eruption had begun to fade. By July 11th the tumor had almost disappeared, as also the *plaque muqueux*, and the eruption was entirely gone. The fissure of the lips was also healed, and the patient left the hospital on the 16th of July in a perfectly satisfactory condition (the cough also was diminished), both as regards her general health and the march of the pregnancy. The treatment was continued uninterruptedly during the first month; after that, the sublimate was suppressed, and the iodide alone continued.

MM. Guérin, Perrin, Verneuil, and Velpeau, also took up arms in defence of mercury. They nearly all insisted upon a *prolonged* treatment, not less than two years, as absolutely necessary to radical cures. M. Guérin therefore disapproves of large doses. He prefers the protiodide associated with opium, but in case that is supported with difficulty, he has recourse to fumigations with cinnabar. He does not believe that inunctions alone are sufficient, while they have the inconvenience of producing salivation more speedily than other methods of administration. M. Perrin, with an experience of 470 cases, treated at Val de Grace, disbelieves that mercury administered in primary syphilis can prevent the regular evolution of the disease, and therefore confines himself to local cauterizations, and only commences general treatment with the appearance of secondary symptoms. He is careful to administer chlorate of potassa coincidently with the mercury in any form. He acknowledges that no treatment is infallible against relapses, but that the physician is simply called upon to be persevering, and reapply the treatment at each outbreak until he has mastered the disease.

M. Verneuil and Velpeau believe in the beneficial effects of mercury at all periods of the disease, and the former declares that salivation is an imaginary phantom. Syphilis *may* exhaust itself spontaneously, but such cases are rare, and generally the patients are exhausted first.

The only person who in any way sustained the views of Desprès was M. St. Germain, who, while professing to believe that mercury does render some indefinite service in syphilis, declares at the same time that he considers it as useless against chancre, that he has a "certain tendency not to administer it in secondary syphilis," and that he always combats tertiary symptoms by iodide of potassium.

It appears, therefore, that not much new light has yet been thrown on this important subject by the debate. The society is waiting to hear the opinion of M. Diday, pupil of Ricord, whose voice would naturally have much influence.

More original views were presented in a recent discussion at Lyons, on the same subject, where several of the members maintained that it was unnecessary to spend much time or thought upon the cure of patients who had fallen a prey to the disease in consequence of misconduct, and that especially such patients should never receive the benefit of gratuitous treatment.

VESICO-VAGINAL FISTULA TREATED BY THE AMERICAN METHOD.

M. Courty, Professor at Montpellier, publishes an account of six cases of vesico-vaginal fistula, successfully operated by the "American method." The *Bulletin of Therapeutics* publishes the details of two that presented unusual difficulties. In one, the fistula, five centimetres long, dated from four years, the urethra was obliterated, and vagino-pubic adhesions existed. There was also a hernia of the bladder. Owing to the adhesions, the operation was exceedingly difficult, the hæmorrhage abundant, and the lips of the wound did not completely close. After a second operation, however, performed upon the gaping part of the suture, adhesion was effected, and a radical cure completed. The treatment lasted four months. In the second case, the patient, a woman 28 years old, had already been operated upon unsuccessfully, and a cicatricial tissue, hard and thick, bordered the edges of the fistula, which was eight millimetres long. In this case also, two operations were necessary.

M. Courty only revives the borders of the fistula, at the expense of the vaginal mucous membrane, carefully avoiding the vesical. For the deep sutures he uses Startin's needles, and for the superficial, Sims'. He leaves a sound constantly in the urethra, and by means of a canula pushed to the bottom of the vagina, has the cavity washed out twice a day with a lotion to prevent suppuration. The wires are withdrawn between the fifth and tenth days.

MISTAKE BETWEEN AN OVARIAN AND RENAL CYST.

The *Gazette Hebdomadaire* quotes a case of a mistake made between an ovarian and renal cyst by the distinguished Dr. Wells of London. A woman of 43 years presented herself at his hospital, to be treated for an abdominal tumor, that two experienced physicians had already pronounced to be an ovarian cyst. They had refused to operate, however, because a loop of intestine was recognized as passing in front of the tumor. On the 4th of August, when Mr. Wells first saw the patient, the tumor had risen to the epigastrium, and the patient seemed threatened with suffocation. He punctured the cyst to her immediate relief, and the tumor and dull percussion sound entirely disappeared. Two months later, the woman returned to the hospital, with the tumor again filling all the abdomen. On the left of the umbilicus was recognized a hard band, which was supposed by some to be a loop of intestine, by others the Fallopian tube. The menstruation was regular; the urine contained mucus and epithelium, but no albumen. The abdomen was largely opened in the median line. The incision of the peritoneum revealed passing in front of the cyst, the transverse and descending colon, intimately adhering to the abdominal walls and also to the cyst; 15 pints of gray purulent liquid were withdrawn from the cavity. The destruction of the adhesions revealed a second cyst, which yielded two pints of clear liquid. Finally, since it was impossible to destroy the deep adhesions, the cyst was left in place and the wound closed. The patient succumbed the next morning. At the autopsy the following state of things was manifest: Four pints of sanguinolent serum and of coagula were effused in the peritoneum. *The uterus and ovaries were perfectly healthy.* The right kidney was hypertrophied, and much softened, a calculus of 40 centigrammes was found in the calix. The left kidney was converted into a cyst more voluminous than the head of a fœtus, containing a single cavity divided by bridles, and whose walls were formed by the renal capsule. The parenchyma had completely degenerated and atrophied.

A precisely analogous case occurred here the other day, at La Pitié, in the ward of M. Belrier. The patient was 48 years old, and feeble, and on this account it was decided that ovariotomy was unadvisable, although an ovarian cyst was diagnosed without any hesitation. Tapping was followed by the complete collapse of the tumor, which, however, resumed its original dimensions in two or three weeks. At the time of the patient's death, two or three weeks after the operation, the cyst contained several quarts of liquid, and occupied all of one side of the abdomen, from the iliac fossa to the hypochondrium. At the post-mortem, this tumor was found to be an enormous cyst of the kidney, whose entire parenchyma was destroyed, and only the capsule left, lined by a serous membrane of new formation, but of sufficient secreting power to reproduce the entire volume of liquid in the course of two or three weeks.

Mr. Wells has profited by his mistake to make a more careful study of the points of diagnosis between renal and ovarian cysts, and has published some most valuable reflections. The diagnosis, he says, should be based on the following circumstances:

1st. Whenever a bridle of intestine is recognized as passing in front of the cyst, it is almost certainly renal, since the ovarian cysts push the entire intestinal mass of it against the vertebral column.

2nd. The ascending colon would be found on the internal side of the right kidney; the left is crossed from above downwards by the descending.

3rd. The urine, which should be subjected to a microscopic examination, nearly always contains mucus, epithelium, pus or albumen, in cases of renal tumors, whilst the menstruation is not disturbed as it is in ovarian disease. (This latter circumstance evidently cannot be relied upon in the numerous instances where the tumor is developed after the ménopanse.)

4th. The bridle, on percussion, is found to be contracted like a cord, and is mobile.

5th. In the case of ovarian cysts, the liquid often escapes by the Fallopian tube, after adhesions have been contracted, while in renal cysts the way of escape is by the ureter and bladder.

6th. Renal tumors appear first in the hypochondria, and develop downwards; ovarian in the iliac fossa, and pass upwards.

Mr. Wells concludes that henceforth no one need make a mistake between the two diseases.

CANCER OF THE KIDNEY, ETC.

While speaking about renal tumors, I must mention a highly interesting case at present in the service of M. Hérard, at Laribaissière, where an inverse mistake in the diagnosis was induced by the ambiguity of the symptoms. The subject, a woman of about 38, entered the ward the 31st of March, presenting an abdominal tumor that occupied the left iliac fossa, and extended in front to the umbilicus, and behind to the spine. A smaller tumor was situated in a precisely similar manner at the right side. The patient had begun to suffer five months before her entrance, with severe pains in the renal and dorsal regions, which were presently followed by the development of the left tumor, which rapidly increased to its present size. The disease had attacked the right side about a month ago. The anterior border of the tumor could be felt distinctly in front; behind the limits were more vague. Clear percussion sound was obtained between the dulness of the tumor, and that proper to the spleen. Also, the mass did not continue into the inguinal region, or pass the median line, so that the idea of an ovarian disease was set aside. The position at the left of the principal mass put the liver out of the question, and the appearance of a similar tumor in the right renal region indicated that a symmetrical organ was invaded. Everything, therefore, led to the belief that the disease occupied the kidney, a belief (as I hasten to say) that so far nothing has contradicted. But the tumor presented quite distinct fluctuation. The complexion of the patient, though pale and chalky, had no tint of special cachexia, and the diagnosis of renal dropsy (*hydronephrose*) was pronounced. A surgeon in consultation agreed in this opinion, and tapped the tumor. There issued, neither urine nor serous fluid, but a small quantity of juice, which, both to the naked eye and the microscope, was evidently cancerous. The greater part of the tumor was, after all, solid.

The patient is still alive, and her condition is liable to great variations. For a long time after her entrance to the hospital she suffered almost continually from pain, which, finally, seemed to be relieved by subcutaneous injections of morphine. A week ago she was a great deal better, sat up, embroidered, felt quite at her ease, but a relapse has just occurred, and she is now about in the same state as when she entered. During the first weeks the tumor seemed to increase, but for the

last six weeks it has been quite stationary. Since the tapping (which did not materially diminish the size of the tumor), the sensation of fluctuation has disappeared, and now the surface of the mass is more uneven, though never hard, or distinctly bosselated. The cancer is evidently an encephaloma.

CONTRACTIBILITY OF MUSCULAR FIBRE.

Before closing my chronicle, I must tell you of some singular experiments that have just been made by M. Rouget upon the contractibility of muscular fibre. M. Rouget commenced his researches on the subject, by the study of the style of the vorticellus, where the muscle consists of a single fibre. This is elongated during life, but under the influence of excitants, or after the death of the animal, the spiral returns brusquely on itself, and is shortened four-fifths, being transformed into a spiral spring, pressed closely together. Experimenting subsequently upon living animals, Rouget found that everything that interfered with the nutrition of the muscles, made them contract. If the main artery of a limb were tied, if galvanic excitement was continued incessantly, if the muscles were subjected to a continually increasing heat or to cold, the result was always the same, *they contracted*. When the contractions were too frequent, the myographion showed that the transverse lines repeatedly approached each other, could no longer separate, but remained, as it were, agglutinated. Rouget declares that the primitive muscular fibre is constituted by an elastic fibre twisted in a spiral, and that the transverse lines mark the curves of this spiral, and not the segmentations of a straight bundle of fibrillar elements, as usually maintained. The state of repose, the normal state of this spiral, is that of the approximation of its rings, which appears to the eye as the contraction of the muscle. The lengthening is the really active process, and can only occur during the vigor of life. The cadaveric rigidity of muscles is precisely the same phenomenon as that occurring when their vitality has been exhausted by heat or cold, or starved out by lack of food. When a muscular fibre shortens, it does so in virtue of its own elasticity, which triumphs over the vital force developed in the act of nutrition. This or any other force that excites motion in the muscles, at the moment that it ceases to act, is transformed into heat, and hence the rise of temperature observed in muscles entering into a state of contraction.

Muscles do not contract in successive undulations or shocks, except at the beginning of the action of an external excitant, or when they are exhausted by fatigue. Contracted muscles seen under a microscope, are found to be perfectly motionless. When they contract by the will, there are no undulations even at the beginning of the period.

The influence of this theory, which reverses the passive and active sides of muscular movement, upon tetanus, chorea, and all diseases of muscular activity, is easily perceived. But M. Rouget as yet attempts no pathological applications.

Un joli mot, as the French say, in conclusion. You are familiar with the name of Charcot, I suppose, and of his intimacy with the distinguished surgeon, Vulpian. The two have so often published together, that their names are inextricably associated to the public ear. The other day a friend of Charcot's observed:

"Charcot has been made happy this morning. He is the father of a son."

"What," exclaimed a bystander, "Charcot and Vulpian?" But it was explained that this time it was Charcot, *tout seul*.

THE ORIGIN OF MODERN ANÆSTHESIA.

I have not yet finished, for I must mention the compliment paid by the *Gazette Hebdomadaire* to the MEDICAL RECORD, as "the most serious medical journal in the United States." When the RECORD ascribes the first (chronological) honor of chloroform to Dr. Wells, the *Gazette* thinks that the question is settled.

P. C. M.

JOTTINGS OF A MONTH ABROAD.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR DOCTOR—Seven weeks ago I was with you in your *sanctum* in Walker Street, as little dreaming of a trip to Europe as of journeying to the moon; to-day finds me on board the St. Laurent, bound from Havre to New York. Summoned by cable-despatch to a sick relative at Rome, I left home at a few hours' notice, reached the "eternal city" in seventeen days, and, with my invalid in charge, came, by easy stages, once more to ship-board. With only four to five weeks abroad, and with another and paramount object of attention on hand, you may well suppose that I have had but little time to devote to medical study and observation, and that I cannot have much to tell you and your readers. Still my visit has not been entirely sterile, and, after fifteen years' absence from Europe, it has afforded me almost as much pleasure as would be enjoyed by a novice. Perhaps a few jottings by the way may be worth *Record*ing, even in a somewhat desultory manner.

I had not before appreciated the danger incurred by pleasure-seekers in Italy, especially during the spring and summer. The relative referred to left home, apparently in good health, in the month of March, and made the tour of Italy with the usual labor of sight-seeing; and any one who has tried it knows how exhausting this is. On the eve of leaving Rome he was seized with fever, from which he had partially recovered, when a hæmoptysis took place, and auscultation of the lungs showed that tubercles, which had probably existed before in a latent state, had been still further developed. He was sent to the Alban Hills, in the neighborhood of Rome, but even there the climate was so depressing that he was daily losing ground, until my arrival enabled him to be brought to a cooler and more healthy region. Nor has this been an isolated case this season. Two very similar ones have come to my knowledge, both happening to American travellers, one of which has already terminated fatally, and the other is likely to do so. Dr. J. Henry Bennet, in his "Winter in the South of Europe," p. 195, says: "Rome is a winter residence for healthy tourists, not for invalids; malaria reigns there, more or less, all the year. Every winter it makes victims, even among the healthy, and the medical practitioners who have been settled there for years say that malarial fever complicates, more or less, nearly every form of disease, slight or severe, that occurs, even during the winter months." These facts should be borne in mind by physicians when advising patients with regard to a foreign tour.

I had hoped to be able to go northward from Rome and see something of medical matters in the north of Italy, and possibly in Germany. I wanted especially to see 'in Florence' Galligo, the author of a most able work on venereal diseases, and Professor Pellizari, who first established beyond dispute the inoculability of syphilitic blood; to become personally acquainted with Drs. Tamburini and Ricordi, in Milan, and to visit the Hospital Maggiore, where the latter is fast making for himself a name by his studies in syphilography. The bright stars in Germany are too well known to require enumeration. My patient, however, was too ill to bear the fatigue of travelling by land, and so I was compelled to turn my back upon all these anticipated pleasures, and

even upon the magnificent fête of the "eighteenth centenary of St. Peter" about to be celebrated at Rome, and start for Paris, viâ Civita Vecchia and Marseilles.

The loss was in a good measure compensated for by the opportunity thus afforded of passing two days at Lyons on the way. It is not often that one has a chance to visit a place so remote from the larger medical centres, although the desire to see such men as Diday and Rollet, and others of the famous medical school of Lyons, would make one put up with many inconveniences to accomplish it.

I visited the Hospice de l'Antiquaille in company with the surgeon-in-chief, Dr. Gailleton, who kindly pointed out the cases of interest, among which were several instances of the communication of syphilis among glass-blowers, through the medium of the mouth-tube used in common by a number of men belonging to one set. The frequency of this occurrence has induced the authorities to adopt certain preventive regulations. Cases of gono-rhœal rheumatism were also unusually numerous in the wards, and several of them in women.

This hospital is admirably situated upon the heights of Fourvières, several hundred feet above the city, and commanding a view of Mont Blanc, at a distance of ninety miles. It is the only institution of the kind at Lyons into which venereal cases are admitted, and hence it affords an admirable opportunity for the study of this class of diseases. Aside from its lunatic department it has three divisions, one devoted to the skin diseases of children, one to venereal diseases of men, and a third to venereal diseases among women. Each surgeon takes these three divisions in order, devoting six years to each, and at the close of his eighteen years of service resigns. This is a bad arrangement on one account, since it leaves some men like Rollet and Diday, still in the prime of life, without a public field for observation or instruction.

Personal interviews with the two physicians just named were most agreeable. Diday I should judge to be about fifty-four years of age. He looks not unlike our friend, Dr. A. C. Post, and has all the activity and vivacity of the latter. He was much interested to know whether anything was doing in America with regard to the prophylaxis of venereal, a subject which at present is engaging renewed attention both in France and England. A novel and rather questionable idea advanced by Diday is the parasitic origin of all venereal diseases, including gonorrhœa. His argument is this: It is the prerogative of organized beings to produce their like; venereal and other contagious diseases reproduce themselves, and hence must be of parasitic origin. Diday expects that this view will yet be confirmed by the microscope.*

I was particularly struck with the fine appearance and affable manners of the handsome Rollet, a younger man than Diday, but who is entitled to rank among the first syphilographers of the present day. Surely, I know of no one who has contributed more to syphilography than he during the last ten or twelve years.

At the invitation of these gentlemen I was present at a meeting of the Academy of Medicine of Lyons, where I found an assemblage of some thirty to forty physicians and surgeons, seated round an immense table, under the presidency of Dr. Bouchacourt, and occupied with a discussion upon the contagiousness of cholera, carried on in a scientific spirit which might serve as an example to some of our medical societies. It was amusing, however, to observe how severe a Frenchman can be in debate, and yet how parliamentary in his language.

* A letter from my friend, Dr. J. H. Salisbury, of Cleveland, Ohio, received since my return home, intimates that he has already accomplished something in this direction.

Arriving in Paris a few days afterwards, of course I made it one of my first objects to see Ricord, the Nestor of the syphilitic world, and one of the few bright lights of twenty years ago still remaining. I was told that I should be likely to find him the least occupied at about eleven o'clock in the evening, when his office hours, which commenced at four in the afternoon, were *nearly* over. Calling at this hour, however, I found his waiting-room still filled with patients, and he afterwards told me that he was rarely through before twelve or one o'clock. Ricord has "aged," as an Englishman would say, since sixteen years ago, but his activity and endurance may be inferred from the amount of work of which he is still capable. If any medical man ever had reason to be satisfied with the well-merited honors that all confer upon him in his green old age, it is certainly he. There was no time to talk over with him any of the mooted questions of syphilis, but there is no doubt (and my friend, Dr. Atlee, of Philadelphia, will please notice the fact) that Ricord now admits in full the recent doctrines upon venereal diseases, including the duality of virus, the contagiousness of the secretions of secondary lesions and the blood, and also vaccinal syphilis. Such was the universal testimony of his friends in Paris, and I afterwards heard the same from Mr. Acton, in London, who had recently spent several days with Ricord, and had freely conversed with him upon these topics. It may be, as I judge from what I heard, that this surrender was somewhat reluctantly forced upon him at an age when he felt he had not the time or opportunity to prolong the contest, but the fact remains the same. I was told in Paris that he still refused to admit the possibility of vaccinal syphilis, but Mr. Acton informed me that he now yields even this.

The most prominent among the younger men at Paris who devote themselves to the specialty of venereal diseases, and the one most likely to succeed Ricord in his position so far as any one can, is probably Fournier, the pupil and ardent admirer of Ricord, and the editor and annotator of Ricord's *Leçons sur le Chancre.* I had the pleasure of accompanying Fournier through his wards at the Hôtel Dieu, and listening to an admirable lecture from him upon renal paraplegia, which was illustrated by a case in his service. He is the author of various articles relating to venereal in the *Nouveau Dictionnaire de Méd. et de Chirurgie pratiques,* now in course of publication by J. B. Bailliere. These articles are not only an excellent resumé of the subject—the best that I am acquainted with—but contain much original matter, and will probably at some future time be incorporated in book form.

From Fournier's lecture-room I went into Maisonneuve's wards, where I found him making his visit and surrounded by a crowd of students. On being introduced to him he stopped to compliment the success of American surgery, and among several instances, mentioned the remarkable results obtained in ovariotomy as compared with the results of the operation in Paris. I suggested that the atmosphere of hospitals was peculiarly unfavorable to this operation, but I soon found that I had touched him in a tender spot, for he immediately began a lecture lasting at least twenty minutes, in which he attempted to show that atmospheric and local influences have nothing whatever to do with the success or failure of any operation, and that everything depends upon the skill of the surgeon! "When we know how to operate in cases of ovariotomy as well as American surgeons," said he, "we shall have equally as good results." One of the internes whispered to me that this was a favorite idea of Maisonneuve, and that I had better not reply to his arguments if I wanted to see anything of his service, since he would keep on

talking all day. Maisonneuve is as fond of using the *écraseur* and his *urethrotome* as ever.

Upon calling to see M. Clerc, I found him an older man than I had anticipated, but probably not over 45; of most agreeable manners, and, with an American wife, well posted in American affairs both civil and medical. Clerc is too well known for what he has done in syphilography to render it necessary for me to say anything on this score. He is now correcting the proofs of the second fasciculus of his work upon venereal diseases. I accompanied him in his visit to the wards of St. Lazare, devoted to the prostitutes of Paris—a privilege rarely accorded even to medical men, and was struck with his skill in diagnosis. I wish I had time to describe some of the interesting cases there seen. I may mention *en passant* that he does not believe in the *chancre mixte*, but this might perhaps have been anticipated from his peculiar ideas as to the relationship of the chancroid and the true chancre.

I have found the lost Pleiad! Bassereau "still lives," the author of the most logical essay upon venereal ever written; the man who first stirred up all this hubbub about unity and duality; who ruthlessly "sent flying" our early ideas as to the influence of idiosyncrasy upon the development of the syphilitic germ, and *who will ever be known and thanked for having done it!* For years it has been a mystery to me what had become of this man. Nothing further appeared from his pen. His name was nowhere seen in the reports of the meetings of various medical societies, at which the results of his labors were discussed. I am afraid to say how many students, just returned from Paris, I have questioned the last ten years as to what had become of Bassereau, and have usually received a cold douche in the reply—"Never heard of him!" The fact is, to speak poetically, Bassereau's personality appeared, like a meteor; his work remained, a fixed star!

Having been born a Yankee, I can now make a "guess" towards a solution of the mystery, and one which I think is not far from the truth. Even Parisian society is not quite free from the prejudice that it is somewhat *infra dig.* for a medical man to make a specialty of venereal diseases. Bassereau, a man of unusually refined tastes and sensitive feelings, published a book which reviewed the whole ground of venereal diseases, and contained the germ of almost a complete revolution in the prevailing views upon the subject; and he instinctively gave it the modest title of "A Treatise upon Skin Diseases symptomatic of Syphilis!" Vain subterfuge. Imagine his horror at finding he was appreciated, and that in spite of himself he had become *venereally* famous! What wonder that he should have shut himself within his elegant apartments in the Rue de Tournon, and found consolation in the beautiful paintings with which his taste for art has adorned the walls!

Seriously speaking, however, Bassereau never intended to make a specialty of venereal. Circumstances led him to investigate certain points connected with it. This he did with the genius innate in him, and he discovered a truth which he gave to the world. This done, his work was accomplished. His book was complete in itself, requiring neither emendation nor addition. The fact which it was intended to prove was generally accepted. The purpose he had in view was fulfilled! He had finished *a good work!*

The reputation, however, which his book gave him, has been the source of no little consultation practice in venereal cases, so that his interest in the subject has been kept up, and I was glad to hear from him that he had already written a complete treatise upon the pathology and treatment of venereal diseases, which he should publish "by and by."

I did not see Auzias-Turenne, who is still living in Paris, as firm a believer as ever in syphilization, which, however, is about defunct, both in France and England; in the latter country especially so, since Boeck's manifest failure during his recent visit there. It is said that Auzias-Turenne still practises his inoculations upon patients in a quiet way, but that they (the patients) are first obliged to sign a paper stating that the treatment was undertaken at their express wish, so that he may be protected against any legal process.

But this letter is already much longer than I intended, and I have left myself scarcely any time or space to speak of London, where, however, I was only able to remain some three or four days, and to do little more than visit the Lock Hospital, and to call upon two of the most noted syphilographers, Mr. Acton and Mr. De Meric. The latter conducts the venereal department of the London Lancet with great ability, and is well known from his Lettsomian lectures, and other contributions on the subject of venereal.

Upon the continent, the modern views of venereal pathology, the duality of virus, the contagiousness of secondary lesions, etc., are almost universally adopted. The same cannot, I think, be said of English surgeons, many of whom, especially among the older men, still adhere to the old doctrines. Mr. Acton, for instance, in his green old age, is still firm in the faith of twenty years ago; but this splendid specimen of a "fine old English gentleman" (in the fullest sense of the word) acknowledges that the time for him to undertake renewed investigation is past. He said to me: "What can I say about all this muddle that you have got venereal diseases into? One of you says one thing, and another, another. My days for professional work are over. I have no hospital for observation and experiment. I only spend my mornings in town, and the rest of my time I am on my farm, in which I am most interested. You talk about the contagiousness of secondary lesions, but I don't see such cases. If you ask me my opinion, I can only reply, 'Ricord says he believes it.' Why doesn't some young man take hold of these matters, and clear them up?"

Notwithstanding this partial retirement from active life, Mr. Acton is deeply interested in the movement for the prevention of venereal diseases which is now going on in England, and he has recently visited Paris for the purpose of examining anew the working of the system there in vogue. It is probably known to many readers of the RECORD, that the parliament of Great Britain has already passed an act which went into operation in December, 1864, and was entitled the "Contagious Diseases Prevention Act." The object of this act was the prevention of venereal diseases in the army and navy, and its operation holds good only for such towns as are military or naval stations. Its general features are that the police of such towns have the power of causing any common prostitutes to be taken to a dispensary to be examined as to their state of health, and, if diseased, of enforcing their stay in government hospitals until cured. Already this law has caused a very considerable diminution of venereal disease in the army and navy, and also among the civil inhabitants of these towns; and it is recommended by the committee of the Harveian Society of London, to which the matter was referred, that the same regulations be introduced in London and other large towns. Even now London has a Lock Hospital for both male and female patients, which has been in existence for more than a century! Is it not time that some provision for this purpose were made in America? But this subject, as well as an account of my visit to the Lock Hospitals, must be deferred to another occasion.

I will only add one word with regard to the endoscope, which does not appear to be used to any extent either in Paris or London, and is regarded as of very little *practical* value, while a catheter still has an *eye* to it, or while the surgeon who is entitled to use a urethral instrument, whether a sound or a catheter, has an "eye in the end of his finger."

Yours truly, F. J. BUMSTEAD.

THE SANITARY CONDITION OF CHICAGO

(FROM OUR SPECIAL CORRESPONDENT.)

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—Favored by a season remarkably conducive to health, and cared for by an energetic Board of Health, our city has enjoyed a degree of immunity from disease, which has never been surpassed since the colonization of the north-west territory. The weather has been singularly fine, with very little of that excessive heat which often renders the summer months so enervating in the prairie-land. Thunder-showers have been infrequent; yet there has been no drought to parch the soil. Above all there has been almost none of that steaming, sultry, equatorial weather, which last year was so favorable to the propagation of miasmatic diseases. Our new Board of Health has displayed commendable vigor. Under their administration, the long-forgotten voice of the scavenger has been again heard in the streets. The gutters and sewers were thoroughly cleaned, and the alleys were purged of manure at an early date in the spring. The bodies of nine thousand eight hundred and thirty-nine dead dogs were deported from the city, and of nuisances a host without number were thoroughly abated.

For the first time in its existence, Chicago has been presentably clean, much to the astonishment of the innocent civilian who had never experienced the good effects of a little military energy and dispatch in the administration of public affairs. In fact, the city is as clean as it can be so long as the great work of providing sewerage, pavement, and water, has not yet reached a point where it can be adequate to the supply of our increasing population. The present condition of our water-supply affords a marked example of the difficulties with which a growing community must contend. Placed in communication, by a magnificent tunnel, with an inexhaustible reservoir of the purest and most delicious water that has ever been carried to any city, we have actually known suffering during the past season for want of that element; and another month will pass before the completion of the new pumps will afford a sufficient supply.

"Shall we have cholera this year?" is the great question which is now upon the lips of every one. In spite of a considerable increase of population, the mortality of 1867 has been much less than during the corresponding months of 1866. During the month of July, the usual increase of bowel complaints has been remarked. There has been a more than common tendency to dysentery. And it cannot be denied that rice-water stools, with vomiting, cramps, and suppression of urine, have been occasionally encountered by some of our most experienced diagnosticians. The Board of Health, while refusing to name these as cases of Asiatic cholera, takes pains to deal with them as if they were such. There can be no doubt that the germs of the disease exist in Chicago, but whether they will slumber innocuous, or whether they shall yet be awakened to direful activity, your correspondent does not venture to predict.

The handsome new building of Rush Medical College is rapidly approaching completion. In magnitude, elegance, and convenience, it is said to excel every other Medical College building in the United States. Were it only possible now to lay aside all fear of competition with the University of Michigan, adjusting the fees to a rational standard, and bringing the course of teaching into conformity with the requirements of an enlightened age, nothing could restrain this rejuvenated institution from its natural position in the foremost rank of American colleges. As soon as the conflict with brick and mortar is ended, it is to be hoped that the representative men of old Rush may be found ready to join hands with those who would have our colleges *express* rather than retard the progress of medical science.

The place of the lamented Amerman in the surgical staff of the County Hospital, has been filled by the election of Dr. Edwin Powell, of this city. Dr. P. is the nephew and successor of the celebrated Professor Brainerd. He served with great distinction in the medical staff of the army during the late war. He has since been connected with Rush Medical College, as Demonstrator of Anatomy, and more recently as Professor of Military Surgery, a position which he resigned to accept the appointment of surgeon to the County Hospital. To this place he brings first class ability, and a reputation second to no other in Chicago.

M.

CHICAGO, August 15, 1867.

LUXATION OF THE ULNA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—In your issue of August 1st, there appeared a communication from Dr. Stephen Rogers, in which is given a lucid description of "a very rare accident," and its treatment under Dr. Rogers's direction at the Demilt Dispensary.

There appear, also, in various parts of this article, remarks which reflect rather severely upon the previous treatment of the case in question in this institution. I deem this not only undeserved, but also unjust. I was present when the patient first applied at this office for treatment; I heard the diagnosis as given by the surgeon taking charge of the case; I witnessed the reduction of the dislocation and the application of the splint, and also myself, on two different occasions, examined the affected joint and questioned the patient as to her ailment. I feel, therefore, that it becomes my duty to state to the profession my knowledge of the case, and to correct any wrong impression that may have been received upon reading the remarks of Dr. Rogers.

The patient is represented to be an "Irish domestic." Personally, I mention her inability to serve in such a capacity, and especially to perform the severe duty of wringing clothes, which is stated to be the cause of the dislocation. She is sadly deformed—a lateral curvature of the spine so distorting the trunk that the ribs of the right side rest upon the crest of the ilium. Her general appearance would also indicate that she was not capable of undergoing any hard labor.

There is one point upon which Dr. R. is evidently very greatly mistaken. To quote from his letter—"Not satisfied with her progress towards recovery, the patient, after waiting many days, finally came to the Dispensary." Dr. R. also states that the patient "presented herself at the Demilt Dispensary on the 19th of June, 1867." Our books will show that her first appearance here was on the 15th of the same month, or just *four days* before she applied at the dispensary.

The dislocation was reduced, and the splint applied on the morning of the 16th of June. The patient was then ordered to report the next morning. This she

failed to do, and nothing has been seen of her at this institution since the application of the splint.

When the patient first made application for treatment she was particularly questioned regarding the cause of the dislocation. In reply to all queries she said, "it came on, and I do not know any cause for it." The surgeon who was examining the joint then turned, and, in a jocular manner, remarked to myself and some medical students who were present, "this, then, must be a case of spontaneous dislocation of the ulna." It was further remarked, that injuries of a similar nature had not unfrequently been presented for treatment at this institution.

In another part of his letter, Dr. R. states that he "restored the bones to their normal position, but without snapping, sudden slipping, or other usual phenomena of the return of dislocated bones to articular cavities." Precisely the same circumstance was observed when the dislocation was reduced at this office. There was no difficulty of retaining the bones in position—no seeming tendency to a recurrence of the dislocation, and the normal relation of the hand and forearm was perfectly restored when the patient left this institution.

What tampering may have been done by the patient herself, or her friends, during the *three days* that elapsed between the time of the application of the splint and the presentation of the case at the dispensary, I know not. But it is probable that the dressings were removed, and on that account she may have felt a disinclination to return to the institution, where, during the time the case was under treatment, I am satisfied all was done that could be accomplished by the most skilful surgery.

Respectfully yours,

NEWTON M. SHAFFER, M.D.,
Assistant Resident Surgeon.

INSTITUTION FOR RUPTURED AND CRIPPLED,
N. Y., August 15, 1867.

GOOD AIR.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR—But for the circumstance that the MEDICAL RECORD is much more generally distributed than the "Transactions of the Academy of Medicine," I would not trouble you to state that in your notice of my paper on *The Economy of Human Life*, in your last number, I am incorrectly reported as maintaining—"that proper food was much more important than good air, or the most salubrious surroundings."—While I do think, and endeavored to show in my paper, that insufficient food in child-bed is a fruitful source of ill health to mothers, and that poor and insufficient food is a fruitful source of mortality among infants and children, I am, nevertheless, far from maintaining that anything is or can be more important to health than good air.

Truly yours,
A. N. BELL.

BROOKLYN, Aug. 19, 1867.

NEW USES OF MICA.—Mica coated with a silver film is now used in this country for large reflectors. Puscher of Nuremberg has suggested the employment of silvered mica for covering curved surfaces, the flexibility of mica giving it great advantages over glass. After being heated, mica loses most of its flexibility, but it then makes a beautiful material for inlaying work. A pretty effect is obtained by scattering small fragments of mica on freshly poured sheets of gelatine, and varnishing it with a dark solution of gelatine. Finely ground mica mixed with a solution of gum arabic may be used for a silver ink.

Obituary.

CHARLES E. MORGAN, M.D.,

NEW YORK.

DIED, on August 4th, 1867, Charles E. Morgan, M.D., in the 34th year of his age, of acute diarrhœa and hæmorrhage of the bowels, after an illness of five days.

In Dr. Morgan, the profession loses one of its most cultivated and able members. His studious habits, and his enthusiastic devotion to science, occasion a profound regret that his life was so short.

His career as a scholar must have commenced very early, as we hear of his prosecuting the study of mineralogy at eleven years of age, under the care of the late Dr. Francis Hawkes, and of the production of a work on natural philosophy at the age of seventeen. In 1854 he graduated at Columbia College, and in 1857 received the degree of Doctor of Medicine at the College of Physicians and Surgeons. He then spent seven years in Europe in the study of medicine and the collateral sciences, under such men as Bernard, Robin Le Compte, Virchow, DuBois-Reymond, and Hoppeseiler.

He returned in 1864, and few were better fitted for their life-work than he.

Since his return he has been engaged in the practice of his profession, giving special attention to diseases of the skin, on which he has frequently lectured; and during the last two years he has occupied a chair on diseases of the skin at the Northern Dispensary, which, we may affirm, was never more honorably filled.

Within this time he had completed a work entitled "Electro-Physiology and Electro-Therapeutics, including an Account of the Electric Fishes," which is in press, and for which he traced on the blocks most of the cuts. Undoubtedly his book will do much towards giving electricity its proper importance in the practice of medicine, which it certainly has not enjoyed heretofore. To illustrate the quiet confidence the Doctor entertained of the thoroughness of his work, it may be worth remarking that about a year since he was urged to complete his book, as it had been a long time in course of preparation, in fear that some one else might publish a similar work in advance of his; to which he replied: "I have no fear of that; there are many points considered in my book which no one else will think of." The statement was so thoroughly founded in fact as not to be in the least degree immodest.

He had contributed somewhat to the medical journals, and had read by invitation an article on diseases of the skin before the Medical Journal Association, a few months since, which appeared some time since in our columns.

He had many projects on foot, and seemed to feel that his mission pointed towards original investigations in medicine, more especially to physiology, as he could devote most of his time to such matters, not being under the necessity of practising medicine for a livelihood. He was not a member of any medical association, and although proposed for the American Microscopical Society, he had not joined it. He seemed to entertain an idea, which had too much foundation in fact, that some of the older medical societies had reached their fossiliferous stage of development, and should give place to younger institutions. In fact, he had made efforts to found a new society, which, unfortunately, had not been crowned with success.

It was a rule with our lamented brother "to do whatever his hands found to do with his might," never thinking that aught worth doing at all should be done less than thoroughly well. As a microscopist he hardly

had a superior in this country. Although an excellent linguist, speaking four or five different languages, he was perhaps more able in mathematics and the physical sciences, of which he was especially fond. He added to all these acquirements a good knowledge of painting.

If he had any mental fault, it was perhaps in overburdening a subject with information—presenting more facts than could be well managed, in his great desire to treat things exhaustively; but as this is an error on the safe side, and as age would have corrected the tendency, we could not but be lenient towards it.

It may not be amiss to state that although he was ambitious to achieve for the sake of the good, he was much stimulated in his work by the pleasure a kind and indulgent mother, his sole surviving parent, experienced in his successes.

Towards his professional brethren, he ever maintained a courteous and modest bearing, which never asserted superiority to the humblest member; ever ready to assist any who loved the science to which he had devoted his life, and tempering all his actions with the gentle grace of the Christian. Let us feel certain that he has received the plaudit, "Well done, good and faithful servant."

His funeral was attended by the medical staff of the Northern Dispensary, at St. Bartholomew's Protestant Episcopal Church, of which he had for years been a consistent member. After which, a meeting was held by the physicians, and resolutions of sympathy and condolence passed, which were sent to his family, and ordered to be printed.

New Publications.

BOOKS AND PAMPHTETS RECEIVED.

A TREATISE ON HUMAN PHYSIOLOGY, DESIGNED FOR THE USE OF STUDENTS AND PRACTITIONERS OF MEDICINE. By JOHN C. DALTON, M.D., Prof. of Physiology and Microscopic Anatomy, in the College of Physicians and Surgeons, etc., etc. Philadelphia: H. C. Lea. 1867.

A TREATISE ON EMOTIONAL DISORDERS OF THE SYMPATHETIC NERVOUS SYSTEM OF NERVES. By WILLIAM MURRAY, M.D., M.R.C.P., London, etc. New York: A. Simpson & Co. 1867.

THIRTY-FIRST ANNUAL ANNOUNCEMENT OF THE MEDICAL DEPARTMENT OF UNIVERSITY OF LOUISVILLE. 1867.

NINTH ANNUAL ANNOUNCEMENT OF THE CHICAGO MEDICAL COLLEGE.

NINETEENTH ANNUAL CATALOGUE AND REPORT OF THE NEW ENGLAND FEMALE COLLEGE. Boston. 1867.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF KANSAS, for 1867.

MEDICAL COMMUNICATIONS TO MASSACHUSETTS MEDICAL SOCIETY. Vol. XI., No. 1., for 1867. Boston. 1867.

Medical Items and News.

COLLEGE OF PHYSICIANS AND SURGEONS.—Dr. Bumstead has resigned the post of Lecturer upon Materia Medica at the College of Physicians and Surgeons, and Dr. James W. McLane has been appointed in his place.

Dr. Bumstead has accepted the appointment of Professor of Venereal Diseases at the same College.

THE BRITISH MEDICAL ASSOCIATION, during the past month, held their annual conference in Dublin, Dr. Stokes, Regius Professor of Physic in the University of Dublin, and President of the King's and Queen's College of Physicians, being the presiding officer. The arrangements for the scientific portion of the business were more complete than on any former occasion. Trinity College and the Colleges of Surgeons and Physicians conferred degrees on the most distinguished guests. An invitation to hold the next annual conference at Oxford was accepted, and Professor Cleland nominated as president. In the opening address on "Medicine," Sir Dominick Carrigan impressed the necessity for greater stringency in registration laws, and censured the facility with which diplomas could be purchased in the United States and in Germany.

MUSTER OUT OF SURGEONS, U. S. V.—The following surgeons of the United States Volunteers, who have been on duty in the Bureau of Refugees, Freedmen, etc., are ordered to be honorably mustered out of the United States service:—J. J. De Lamater, A. C. Swartzwelder, W. R. Dewitt, M. K. Hogan, Charles J. Kipp, J. W. Applegate, and Patrick Glenan. Dr. Robert Fletcher, Surgeon, United States Volunteers, is also ordered to be honorably mustered out. The order leaves but one surgeon, U. S. V., in service. The few vacancies existing in the regular corps will probably soon be filled.

THE AMERICAN PHARMACEUTICAL ASSOCIATION will hold its annual meeting at the University Building in this city, September 10th, 1867.

DEATH OF DR. J. MASON WARREN OF BOSTON.—Dr. Warren died of internal cancer complicated with intussusception, August 19th, in the 56th year of his age.

REPORT OF THE EXAMINATION OF VESSELS ARRIVING AT NEW YORK.—There has been compiled at the statistical bureau of the Treasury Department an abstract of the report of the examinations of vessels having on board passsengers other than cabin passengers, which have arrived at the port of New York during the month of June, 1867, from which it appears that the total number of vessels examined was eighty-six, of which forty-two were steamships and the remainder sailing vessels. The average length of the steamship voyages was thirteen and two-third days, and of the sailing vessels thirty-nine days. The total number of passengers brought was 39,078, of which 22,822 were males; 6,566 were under eight years of age. The total number of deaths was 117 males and 59 females. Of the entire number 84 were under eight years of age. The abstract states the mortality of the adults was not unusual, but that of the children calls for investigation, being nearly one and one-third per cent. of the whole number brought over. A number of the vessels brought more steerage passengers than the law permits, and in several instances they were reported for prosecution. A report concerning the Hamburg ship John Bartram, shows that nineteen deaths occurred, of which six were children, and that they were caused by bad water and food, and want of care and attention.

METEREOGRAPH.—Among the objects of great interest to scientists in the Paris Exposition were the diagrams made by the instrument invented by Father Secchi of the College of Rome, for registering automatically the changes in the temperature, pressure, moisture, and the motion of the atmosphere.

YELLOW FEVER IN TEXAS.—The epidemic of yellow fever which has been raging in Indianola and Lavacca, Texas, according to the latest advices of the secular press is now on the decline.

INTRA-LARYNGEAL SURGERY.

By J. SOLIS COHEN, M.D.,
OF PHILADELPHIA.

No. II.

THE APPLICATION OF SOLUTIONS TO THE UPPER AIR-PASSAGES.

Local applications to the throat are most frequently made in the form of solution. They are applied by means of a mop, sponge, or soft brush; or by means of a syringe, or douche; or broken up into a fine mist by means of the nebulizer. The first of these methods is that most generally employed, the sponge being used more frequently than the mop or the brush. If a brush is employed, it should be one formed of a good quality of camel's hair, or badger's hair, and should be well made. Brushes, made of glass, are occasionally employed with corrosive solutions, but there is always danger of the occurrence of injury or embarrassment from the detachment of some of the glass filaments, an occurrence, however, which is said to be infrequent. I have never used these, preferring to have a good camel's-hair pencil destroyed, to running any risks with such brittle material.

The most suitable substance for the application of solutions in the great majority of cases, is a small piece of soft surgical sponge of the finest quality. It must be strong enough to resist a good deal of tension without tearing, in order to avoid liability of its being caught and torn off, so as to cause mischief. When large surfaces are to be washed over, a long-haired brush, the hair of which may extend an inch or an inch and a half from the quill portion, and squeezed at the free end, will be more suitable than the sponge, especially when the parts are very sensitive and the friction of the sponge would produce more irritation. Where a small circumscribed spot is to be touched, a delicate fine-hair pencil answers the purpose. For a general application, if a hair pencil be employed, it should be large enough to take up from five to fifteen minims of fluid. If a decided contact with a diseased surface is desired, such a contact as is produced by moderate pressure, a sponge will be the most advantageous, as it will better allow of pressure; and if it is intended that the application should force a portion of the fluid out upon the diseased surface, the object will be better accomplished with the sponge, as it can be made to absorb a larger quantity of fluid than can be taken up by the brush. In certain cases, a mop, made by unravelling portions of a strip of linen, will be the most convenient medium of application.

Whatever material be employed, care must be taken to see that it is firmly secured to a staff, so there will be no chance of its becoming separated, and this is especially to be guarded against when the interior of the larynx is to be operated upon. A stout piece of whalebone, about the thickness of a writing-quill, and of the proper length and shape, forms the most ordinary stem, and is very convenient. A stout wire of silver, or German silver, firmly secured in a wooden or other handle is also often used, and is perhaps preferable to the whalebone on account of its greater rigidity, besides which the shape of the curve can be readily altered to meet varying indications. The whalebone staff can be bent to any desired shape by first dipping it into boiling water, and allowing it to remain there a few moments; if it is allowed to remain in the hot water too long, it will become too flexible, and curl round like a piece of tape; should this occur, it may be hardened again by immersion in cold water. If the stem to be used be of hard vulcanized rubber, it can be given the desired curve by previous immersion in hot water, or by holding it over a flame for a few minutes. A bit of sponge may be fastened to the probang in several ways; by sewing it on through holes drilled through the extremity of the stem, or by tightly winding a thread round and round it, in which case, the extremity had better be a little bulbous. The plan which I prefer, is to have three grooves cut round and round near the extremity of the stem, and to wrap around the sponge iron wire forced into the grooves, which forms a very secure attachment, less liable to become acted upon by the corrosive solutions than threads of cotton or silk, and thus allow the sponge to be pulled off. A brush may be firmly attached to a stem, by dipping the quill portion, which should first be cut down so as to be no longer than is absolutely necessary, into hot water until it becomes moistened into pliability; then, while in this condition, it is to be placed upon the stem and tightly bound into the grooves by thread or wire.

Another method of employing a brush or a sponge, is to use a staff terminating in a two-bladed forceps, serrated and furnished with prongs, so as to hold on firmly to the brush or sponge, the grasp upon which is tightened by a ring screwing over the forceps, or compressing the blades by a strong bayonet-catch. If desirable, this stem can be made flexible so as to avoid injury to the patient when making an involuntary movement at the moment the instrument is within the larynx, and also to facilitate pushing it on through the glottis against a patient's resistance. Another plan is to seize t e sponge between the blades of a pair of laryngeal forceps with a spring-catch in closing, so as to prevent separation of the blades while the instrument is in use. I am in the habit of employing a delicately made, properly curved spring forceps, acting in the same manner as the artery spring forceps, in which compression of the handle separates the blades which are tightly pressed together by the recoil of the spring, holding the brush or sponge with a firm grasp; and which can be held between the thumb and fingers exactly in the same manner as if it were a sound or probang. If it is deemed desirable to employ a more delicate sensation of touch than can be conveyed by an instrument held between the thumb and fingers, the staff, which should then be much shorter, may be screwed on to a thimble fitting the forefinger as in Fig. 1, which will thus convey the tactile sense with more distinctness. When the sponge is not attached, the instrument becomes a sound. Dr. Elsberg, of New York, has adapted for the same purpose, a spring-ring for the terminal phalanx of the forefinger, like the ring to which the conjunctival scarificator is sometimes attached; to this ring is rivetted a stem composed of two pieces of watch-spring bent to the proper shape, the extremities of which are forked by having a V-shaped piece cut out, so as to prese two sets of prongs, which are bent at a right a

Fig. 1.

towards each other, so as to grasp the sponge when placed between them; a slide passing round the two springs, and a jam sliding between them keep the teeth firmly fixed in the sponge. This instrument is flexible enough, and readily communicates the sensation of touch to the finger. Sponge-holders are preferable to to any sort of probang, because they admit of ready removal, and removal of bits of sponge; so that the same piece need not be used twice, even upon the same individual.

The size of the sponge will vary according to the use to which it is to be put; for circumscribed applications it should be no larger than absolutely necessary; for general application, and where it is intended to press some of the fluid out of the sponge, it should be much larger; if it is to be passed between the lips of the glottis, it should not be larger than a good-sized pistol-bullet, and should be somewhat egg-shaped, so as to facilitate its passage. Every time a sponge is to be used, it should be pulled upon, to see that it is firmly attached to the stem or holder; before use, it should be dipped into plain water, and after becoming saturated should be squeezed dry, so that it will absorb plenty of the medicated solution when dipped into it. Before making an application it is well to press against the parts a soft bit of sponge from which plain water has just been squeezed, in order to remove from the surface any secretions or deposit, and thus secure more thorough contact of the remedy to the diseased structures. In cases of ulcerations in chronic laryngitis, especially of the scrofulous and syphilitic varieties, where there is considerable dysphagia, the difference in result from attention to this particular, and neglect of it, will be found very marked.

No special rules are necessary to be given for the application of a sponge or hair-pencil to the portions of the throat anterior to the larynx; they can be readily exposed and swabbed. Care should be taken to make the application as swiftly and gently as is consistent with thoroughness; there is little to be gained from the employment of force; a little manipulation will soon accustom the parts to the presence of a foreign substance.

For making applications to the lingual surface of the epiglottis, its border, some portions of its laryngeal surface, the upper portion of the laryngeal aperture, and the mucous membrane covering the cartilages of Santorini, it is not always necessary to employ the laryngoscope. If a well-constructed tongue-depressor be employed, of such shape as described in a previous article (see the MEDICAL RECORD, Vol. I., p. 348), it will often be found practicable to force down the base of the tongue in such a manner as to expose a considerable portion of the epiglottis, and not infrequently its entire lingual surface. This requires a little knack, perhaps, in the handling of the depresser, but is very readily acquired. The instruction I give my pupils is, "Press the base of the tongue downwards and forwards as if you were going to force it out under the chin. The patient should sit opposite a good light, natural or artificial, direct or reflex, so that when the mouth is well opened the fauces are well exposed; and the operator should stand in such a manner as to look down upon the pharynx from above, not to look into the mouth horizontally; then the tongue-depressor is to be applied so that a firm hold is taken on the base of the organ, and the effect is to be made again and again to depress the tongue sufficiently; as long as each attempt exposes more and more of the posterior pharyngeal wall, it is safe to continue the manipulation, and finally the crest of the epiglottis will be seen behind the tongue, and repeated efforts may expose its entire glossal surface. If this method be unsuccessful, the epiglottis may be touched or titillated with the extremity of the tongue-depressor, which will induce reflex movements of choking, so as to raise the larynx, and then the larynx can be raised sufficiently, sometimes, to expose a large portion of the aditus laryngis. While this manœuvre is being accomplished with one hand, the proper application can be made with the other to any morbid appearance. The same manœuvre suffices for making applications to ulcers, or other morbid appearances upon the pharynx, which may have been discovered upon laryngoscopic examination. Where morbid processes cannot be exposed in this way, it will become necessary, of course, to have recourse to the principle of reflexion. For a general application to the interior of the larynx or trachea, recourse to the laryngoscope is not absolutely necessary, though more safe than the method introduced with so much success by the late Dr. Horace Green, of New York.

Before making any effort to introduce an instrument within the cavity of the larynx, however, it is exceedingly desirable to become familiar with the exact position occupied by the epiglottis, for this valve is sometimes quite erect, and at others very much depressed; indeed, it is a matter of question in certain medical circles whether a physician is at all justified in making an attempt to pass an instrument into the laryngeal cavity without previously satisfying himself of the normal position of his patient's epiglottis. Where a laryngoscope is at hand, the point in question can be very readily determined; where such an instrument is not of convenient access, the attempt should be made to expose the epiglottis by the method described above; should this fail, the forefinger of the operator, or a strong bent probe should be employed as a lever to keep down the base of the tongue, and if not successful with the tongue retained within the mouth, the same means may be tried with the tongue extended, care being taken to interpose something between the lower teeth and the tongue, so as to prevent injury to the organ from pressure on the incisors. Should this method fail, the forefinger should be passed along the base of the tongue until it reaches the epiglottis, which will be easily recognised by the touch, with which sense its position can be determined also. In such cases the epiglottis may be pulled forward by the forefinger of one hand, which can be used as a guide for the passage of an instrument, over the finger and epiglottis into the larynx; and this method is often the only one at all practicable in making applications to the larynx of the child, in which cases the mouth may be kept open by a mouth-distender or speculum; or the precaution should be taken to protect the forefinger and hand by a towel or handkerchief from unpleasant impressions of the little one's teeth.

The readiest method to pass the probang into the larynx without the use of the laryngoscope, is as follows:—First, determine the position of the epiglottis in the manner described, or any other manner; then depress the tongue with a strong tongue-depressor; if it exposes the epiglottis, so much the better; as the patient takes an inspiration pass the instrument in the middle line until its point has passed behind the position assumed by the epiglottis; then telling the patient to make a prolonged sound of the diphthong œ, depress the base of the tongue by a movement which shall drag it forwards at the same time, and sink the point of the probang downwards and forwards by a vertical movement of the wrist, which shall bring the back of the hand all but in contact with the patient's face. If it is intended to pass the glottis, the patient must be directed to take an inspiration at the moment the probang enters the larynx; this opens the glottis, and permits the pas-

sage of the instrument. The moment the instrument has entered the larynx, spasm takes place, the epiglottis shuts down like a trap-door upon the foreign body, and the patient feels and exhibits the symptoms of impending suffocation. In withdrawing the instrument, the resistance of the epiglottis is felt; and if it has passed the glottis the resistance of its lips will be previously distinguished. The sense of constriction usually described as proof of entrance, and ascribed to the spasmodic closure of the glottis in withdrawing the instrument, is usually due to the pressure of the epiglottis upon it, as I have repeatedly verified with the laryngoscope, during my own manipulations. The distress caused by the first passage of the glottis by a probang is often extreme in degree, the sense of suffocation remaining for some time; but it becomes less and less at each succeeding application, until eventually nothing ensues but a slight paroxysm of cough, sometimes a mere clearing of the throat. If the glottis has been passed, and it is desired to swab the trachea, a single motion down the tube and out again is all that is requisite; to move the probang up and down two or three times, as if the windpipe were a "chimney flue" requiring cleansing, is a procedure as unnecessary as it is inelegant. In persons with thin necks, the passage of the sponge down the trachea can be seen through the integument. The right bronchus has been swabbed in in this way by Dr. Horace Green, and others, and even a tube has been passed into this bronchus for the purpose of throwing in an injection. I have never had occasion to make an attempt of this kind, but I have repeatedly reached the bifurcation of the trachea of a lady who was relieved by this method of a chronic laryngo-tracheitis, said to be of nearly forty years' duration.

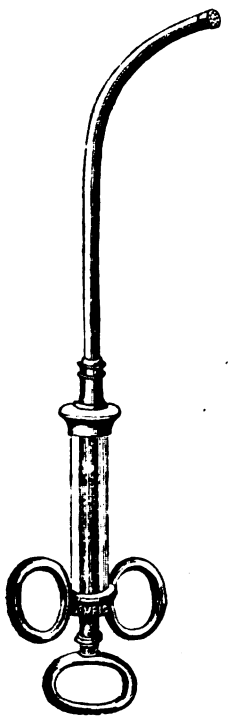

Fig. 2.

The substances most frequently applied by the sponge, mop, or brush, are solutions of nitrate of silver, sulphate of zinc, sulphate of copper, chloride of zinc, tannic acid, persulphate of iron, etc.; the nitrate of silver being employed most frequently. The method of treatment is applicable to cases of chronic laryngitis, follicular and ulcerative; laryngo-tracheitis; pseudo-membranous laryngitis; syphilitic affections of these parts, etc. In withdrawing the sponge, the tongue and pharynx are often touched involuntarily, and this excess of fluid may be removed in part by gargling with suitable articles, such as salt and water after nitrate of silver, milk and water after iodine, etc.

In cases of limited ulcerations, moist excrescences, etc., where the application is to be limited to the points diseased, they are to be made with the aid of the laryngoscope. If a mere momentary contact is required, a very fine hair-pencil may be employed; if longer contact is requisite, it should be made with a small piece of sponge, no larger than is absolutely necessary, fastened in an appropriate sponge-holder. The hair-pencil is more apt to permit a drop of fluid to fall from it, and this may drop into the larynx before the application is made.

Another method of applying liquids to these structures is by means of the syringe. The so-called catarrh-syringe, manufactured by the Hard-Rubber Company, may be employed for this purpose, but the barrel is so large as often to obstruct the view. The most convenient instrument is the syringe of Tobold, Fig. 2, the nozzle of which is of hard rubber, with a silver tip perforated by several holes to permit of the better distribution of the fluid. The barrel is of glass, and if desired, the piston-rod can be graduated so as to permit of great accuracy in the amount of solution to be employed, if this point be deemed of consequence. The rings on the barrel are for the first and second fingers; the ring on the piston-rod for the thumb. Its manner of employment is obvious. This instrument is sometimes made with a laryngeal mirror in the curve, and the contents are projected from several apertures, which open on the rim of the mirror. A somewhat similar combination of laryngoscope and syringe has been devised by Binz. Türck's syringe is similar to Tobold's, but the nozzle has but a single aperture, over which a bit of sponge is tied. It is used in the same manner; but by merely dipping the sponge into a solution without drawing up any of the fluid by the piston, it can be used as a probang.

For the administration of a douche into the larynx, etc., in the form of a very fine spray, and which shall irritate the parts less than an injection from a syringe, the best instrument which has been devised is the laryngeal douche of Gibb (Fig. 3), which consists of a silver tube, with the proper laryngeal curve, to the free extremity of which there is screwed on a platinum bulb, perforated with a number of openings so fine that they cannot be seen without the aid of a lens; the straight end of the tube is fastened by silver wire within the neck of a little rubber ball. The instrument is charged by dipping the bulb into the solution while the ball is compressed, and then releasing the ball until a sufficient quantity has been drawn into the tube. In employing the instrument, it is held by the neck of the ball, between the middle phalanges of the first and second fingers, the ball of the thumb being applied to the base of the ball, and when it has been placed in position it is discharged by compressing the ball with the thumb. The spray produced is as finely divided as that made by the various nebulizers in use, for purposes of preparing solutions for inhalation, and the contact of the spray produces less spasm than any other method of medication. It is admirably adapted to making a general application to the larynx or trachea, especially valuable when the structures are very sensitive or irritable, and contact with the sponge or brush would induce pain, and it can therefore be employed when the use of the sponge would be impracticable.

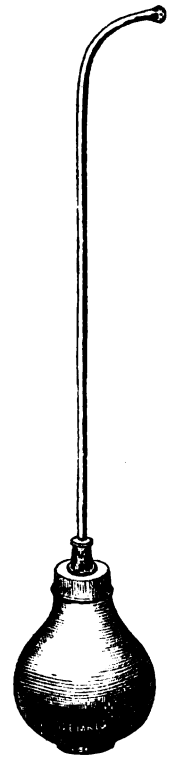

Fig. 3.

These syringes and douches can be employed for introducing solutions into the larynx, when the depression of the epiglottis is so great as to preclude admission

to a sponge or hair-pencil. The method of treatment is applicable to cases of general inflammation, acute or chronic; to alterations of structure; inflammatory affections of the vocal cords and pseudo-membranous laryngitis. Dr. Gibb, in the last edition (London, 1864), of his work on *Diseases of the Throat and Windpipe*, states, p. 232, that he has recently employed the spray of a solution of nitrate of silver (thirty grains to the ounce), as an injection into the larynx and trachea in croup, and the severity of the symptoms were so speedily diminished that he almost doubted whether the disease was actually croup! yet all the well-marked symptoms were present.

By causing the patient to utter a vocal sound at the moment of projecting the fluid from the instrument, we avoid its entrance into the trachea in affections of the vocal cords and parts above them. I have frequently succeeded in overcoming paralysis of the muscles, moving the vocal cords in that form of aphonia, known as functional, by means of an application of the spray of sulphuric ether from the laryngeal douche; and I have also employed for this purpose solutions of iodine, nitrate of silver, and astringents, with satisfactory results, as have also followed the use of the same remedies applied by the sponge. The mechanical effect of the sponge or the douche has doubtless had much to do with the effect, though some amount of credit must be allowed to the stimulus which was employed with them. When ether is used with a douche of this kind, or with a syringe made from vulcanite, the solvent action of ether upon rubber must not be forgotten, and eventual destruction of the rubber portion of the instrument must be expected.

Another method of applying a douche to the larynx is by means of some modification of the Bergson insufflator used for the nebulization of liquids. These tubes are so arranged as to be readily introduced within the larynx, where the distribution of the nebula takes place; or they are so constructed that they can be held over the laryngeal entrance, and the spray be propelled into the larynx without contact of the instrument with that tube. One of the best instruments of the latter kind, and one which can be used by those who would be unable to pass an instrument into the larynx, is the spray-producer of Maunders (see illustration, MEDICAL RECORD, Vol. i., p. 219). This instrument consists of an India-rubber ball, perforated at its base, so as to admit of instantaneous refilment of air when emptied; an upper or air-tube communicates horizontally with the ball, and terminates at its other extremity in a capillary opening, turned downwards just far enough to cover the capillary extremity of a second tube running under the first one; this lower tube at its other end does not communicate with the ball, but dips down into a small vial, which slides upon a pin fastened to the upper tube. In using the instrument the vial is partially filled with the solution to be employed; the instrument held much as the laryngeal douche, between the first and other fingers, is passed into the mouth, until its point all but reaches the posterior wall of the pharynx, and then the ball is compressed by the thumb, which forces the air to escape through the upper tube, while, in passing, the capillary aperture of the lower tube creates a vacuum, forcing the liquid to issue from the little reservoir, and, as it escapes, this liquid is propelled downwards, in the form of spray. By altering the direction of the capillary extremities of these tubes, the spray may be forced in any desired direction. I notice that many of these instruments, as the laryngeal douche and spray-producer, as well as the insufflator, to be described subsequently, are furnished with an egg-shaped rubber ball, similar to those in certain forms of anal syringes. These balls have to be held in the palm of the hand, and then compressed by closing the hand upon them, a motion which invariably disturbs the position of the point of the instrument to a considerable extent, and necessitates a very awkward manner of introducing the instrument. The shaped ball I employ is seen in Fig. 3, in connection with Gibb's laryngeal douche.

Still another method of introducing solutions is that of Von Bruns, who uses a properly curved tube, drawn at one end to a fine aperture; to the other end a piece of rubber tubing is attached. The fluid is drawn up by suction with the mouth, and discharged by blowing through the tubing, an inelegant method of procedure.

All these instruments are improvements upon the method of Trousseau and Belloct, who employed an anal syringe for this purpose, and of Erichsen, who also invented a laryngeal syringe.

By turning these instruments round, or upside down, as it were, and altering the curve if necessary, they become converted into naso-pharyngeal syringes, or douches, for the treatment of affections of the posterior nares and naso-pharyngeal space.

In using corrosive solutions, as of nitrate of silver, acid nitrate of mercury, etc., the portion of the instrument with which the material comes in contact should be of gold, platinum, glass, or vulcanite.

Solutions adapted to the treatment of chronic affections of the upper air-passages should be strong; for instance—of nitrate of silver, grs. 40, 120 to the ounce of water; sulphates of copper and zinc, grs. 30, 80 to the ounce; chromic acid, grs. 40, 120 to the ounce, etc. Weaker solutions are not of much service. If a stronger application is required, the sponge may be moistened, and then rubbed upon the salt, so as to secure a very concentrated solution. For syphilitic affections, the best local application is a solution of the acid nitrate of mercury, one part to from five to twenty of water, according to the indications. Where an application is made, a second application is not usually necessary until all beneficial action from the first has ceased, which may be one, two, or three days, or longer, according to circumstances.

A NEW MODE OF TREATING UMBILICAL HERNIA OF INFANTS.

By A. G. FIELD, M.D.,
IOWA.

IN the treatment of a case of umbilical hernia in an infant, some time since, I experienced but little benefit from the usual appliances, and finally resorted to the use of adhesive strips only, with which a radical cure was effected.

Since then, the plan has been adopted with success in the treatment of other cases, and its simplicity may justify its publicity, and induce others to give it a trial. It is based upon the assumption that there are two indications to be met: the support of the parietes of the abdomen, and the production of a plastic exudation at the point of injury.

Two strips of adhesive plaster of sufficient length are to be applied to the abdomen, each reaching from the crest of the ilium on one side to the hypochondrium on the other, both crossing over the umbilicus. In the application of each, the umbilicus is to be pressed well down by the finger of the surgeon, while the strip of plaster, one end of which having been previously attached, is drawn firmly over it, and secured, so as to cause an inward fold of the integument at the point of injury, thus closing the aperture, and at the

same time constituting a *pad* of the corrugated tissues of the abdominal wall.

By re-applying the strips when they became loosened, and continuing the treatment a few weeks, radical cures resulted.

ON SOME OF THE INDICATIONS FOR THE

USE OF THE EUSTACHIAN CATHETER.

By O. D. POMEROY, M.D.,
NEW YORK.

THERE seems to be a wide-spread prejudice against the use of the Eustachian catheter, especially amongst general practitioners. In looking over works on the diseases of the ear, much will be found in condemnation of this practice; even if it is admitted to be occasionally justifiable, the dangers from its use are so dilated upon, as to frighten any but the boldest from attempting catheterization.

More frequently is this the case with English writers; and American physicians, regarding them with greater favor perhaps, are especially in danger of adopting such erroneous notions.

The Continental surgeons, however, almost unanimously favor its use.

Perhaps one cause of this wide-spread fear of catheterization has arisen from two cases, supposed to have been killed by its use in London, more than twenty years since, and reported by Turnbull, of which Mr. Troltsch remarks: "It is hard to see, from the published account of the autopsy, how the accident occurred." In spite of this, however, it has been quoted in almost every book on the subject since. Two cases by Troltsch, and one by Pitcher, have been recorded, in which emphysema, more or less extensive, has resulted from the use of the catheter; the air being again absorbed, without serious consequences. Occasionally laceration of the mucous membrane and moderate hæmorrhage have resulted.

I have not heard of a case from any surgeon in this country, in which mischief has been done by the catheter when judiciously used. In fact, American surgeons have in public assemblages declared that they have been prejudiced against the use of the catheter, but employ it much more frequently now than formerly! My own experience in the matter may have been sufficient to give me a prejudice for or against its use. I have never met with a single untoward accident; occasionally a little pain has been caused, or the most trifling hæmorrhage. In the case of children, it will be somewhat more difficult. My own practice is to hold the child's head firmly between the knees, when, in spite of struggles and cries, we may succeed in its introduction. (The best mode of introducing the catheter is Kramer's, described in Troltsch's work on the ear, translated by Dr. Roosa.) Politzer's apparatus has superseded the catheter in a great number of cases, and when it succeeds, of course catheterization is unjustifiable. Many times a patient presents himself with only one ear affected; the tube may be so impervious as not to allow an interchange of air between the throat and cavity of the tympanum; you very properly try inflation by the Politzer apparatus and succeed—at the expense of injuriously inflating the well ear, or you do not succeed at all, and must eventually use the catheter; you wish to inject medicated vapors or gases, and the injection goes into the well ear more than into the diseased one, most likely doing mischief; you will not then hesitate to use the catheter. Again, Sir Astley Cooper is reported by Sir William Wilde to have said, "Whenever the patient is himself able to inflate the tympanum, never use any artificial means to do so; it is unnecessary, and may be injurious."

Within a few days I have observed a case which disproves this proposition. The patient was somewhat deaf in both ears from myringitis and inflammation of the cavity of the tympanum, with partial closure of the tubes, worse in the left, to which treatment was principally directed. He could inflate both tympani easily, although that was not the case at first, by holding his nose and making a forced expiration; still there was no improvement in the hearing of the left. I then tried the Politzer, which forced in the air much more strongly, so much so as to cause momentary pain and deafness to the right ear, without improvement in the other; I then tried the catheter in the left, and by vigorous pumping of air through it, succeeded in much improving the hearing. The membrane had, by the inflammatory thickening, become so rigid and immovable as not to be pressed into a normal position (it having become sunken by the disease), except by the catheter.

A new method of treating diseases of the cavity of the ear by means of a medicated spray, in the same manner as in inflammations of mucous membranes elsewhere, has been devised, and to accomplish this, the spray *catheter* must be used; so we infer that any person practising aural surgery, with anything like thoroughness, must needs use the catheter, if not frequently, occasionally, and I am confident that every man capable of using this instrument with even a moderate amount of skill, must coincide with this.

Reports of Hospitals.

BELLEVUE HOSPITAL.

POLYPUS OF THE RECTUM.

By D. McLEAN FORMAN, M.D.,
HOUSE SURGEON.

POLYPUS of the rectum, although a somewhat rare disease, is an important one to be acquainted with, inasmuch as it often produces most severe symptoms, and at the same time is easily remedied.

The most simple form in which a polypus is seen, is where there are one or more short processes, as it were, of the mucous membrane standing out prominently in the cavity of the rectum. These bodies are usually situated in the cavity of the rectum above the internal sphincter, produce little uneasiness, cause very little inconvenience, and therefore do not demand the attention of the surgeon.

A form of polypus very rarely met with is where the growth is warty, composed of an aggregation of small lobes arranged upon a peduncle, just like a bunch of grapes, and upon microscopical examination being chiefly or entirely epithelial.

The vascular polypus is, perhaps, of most frequent occurrence; it is chiefly met with in young children. The tumor varies in size from a cherry to a pea; is of a bright color; its structure is fibro-cellular and eminently vascular. It is usually situated within a short distance of the anus. The symptoms which this form of the disease produces is the prolapse of the tumor when the patient evacuates his bowels, and hæmorrhage of a more or less profuse character. The occurrence of this loss of blood in a child should lead to a careful examination of the rectum, for if the tumor be seated high up it will recede after evacuation of the bowels, and thus escape observation. It is necessary,

therefore, to make the examination immediately after the evacuation of the rectum by medicine or an enema.

CASE OF POLYPI OF THE RECTUM.

Wm. H——, æt. 16 years, was admitted to Bellevue Hospital, July 22, 1867. The patient is a pale, anæmic, sickly-looking boy, has an anæmic cardiac murmur, œdema of both lower extremities, and is very weak. Urine healthy. He states that he has been troubled with a protrusion of the bowel when he goes to stool ever since he was a little boy. At times he has profuse hæmorrhage from the bowels and is greatly prostrated thereby. He complains of pain in his back, and says he has a good deal of pain about the anus when he evacuates his bowels. Soon after admission an enema was administered, and he was directed to force down all the rectum he could. Upon examining him after the enema, there was found to be a flesh-colored mass about the size of a man's fist, presenting very much the appearance, except in color, of the head of a cauliflower, protruding from the anus. Upon examination, this mass was found to be composed of the mucous membrane of the rectum, and several hundred polypi, varying in size from a pea to a very large bean, attached to the mucous membrane by small pedicles, the interspaces being filled with a gelatinous mucus. Upon removing several of the smallest ones for examination, they were found to be extremely vascular, and in texture fibro-cellular. Upon introducing the finger in the rectum, apparently healthy mucous membrane could be felt above the polypi about an inch above the sphincter. This mass of polypi and mucous membrane protrude from the anus every time the boy has a passage from his bowels, and frequently bleed when he walks about, but are easily reduced by himself, several ounces of bloody mucus escaping after each reduction.

Treatment.—Good nourishing diet; syrup ferri iodidi and quinine.

July 31.—Patient is suffering a good deal from his disease, and his general condition is now extremely bad and becoming worse every day. To-day, the patient being seen by several of the attending surgeons, Dr. Sands, at their approval, ligated the mass by passing several strong ligatures through it near the junction of the healthy and diseased mucous membrane, tying them tight so as to strangulate it. After the whole mass had been included in the ligatures, most of the polypi were removed with the scissors and the rest returned within the anus. *August* 1.—The operation has been followed by a good deal of constitutional disturbance. Pulse 140 to 160, and very weak. Skin hot and dry. Tongue a little dry and furred. Complains of pain about the anus. He is kept moderately under the influence of stimulants and opium. *Aug.* 2.—There is but little change in his condition; he has vomited several times during the day. *Aug.* 3.—The patient is better to-day. Has no evidences of peritonitis. Bowels moved three times last night; none of the polypi were voided in the stools. Still complains greatly of soreness about the anus. *Aug.* 14.—Patient has improved daily, several of the ligatures having come away, and to-day several polypi were passed with the contents of the rectum. *Aug.* 23.—Upon introducing the finger in the rectum, one large and several small polypi can be felt, but they give him no trouble, and he is unable to protrude them. He has had no more hæmorrhages since the operation. There is no evidence of a stricture of the rectum. His health is greatly improved, and at his request he was to-day discharged from the hospital and went to his home in the country.

Original Lectures.

ON ABSCESS.

By ALFRED C. POST, M.D.,

PROFESSOR OF SURGERY IN UNIVERSITY MEDICAL COLLEGE.

GENTLEMEN—The subject of my lecture to-day is abscess. This term is used to denote a circumscribed collection of purulent matter in a cyst or sac, which is produced by inflammation. It occurs most frequently in parts which abound in cellular tissue. The inflamed part first becomes infiltrated with fibrine or liquor sanguinis, and then in the midst of its substance a small cavity is excavated by ulcerative absorption, and the cavity so formed is filled with pus. By progressive ulceration, the cavity becomes gradually enlarged, and the quantity of contained pus is increased in the same proportion. The ulceration involves chiefly the wall of the abscess which is nearest to the external surface of the body, or to some mucous canal which lies in its neighborhood; and in this manner the cavity of the abscess approaches nearer and nearer to the surface, until finally, when left to itself, it discharges its contents, when its opposite walls become approximated, and ultimately united with each other, chiefly by the process of granulation. Abscesses are often attended with marked embarrassment of the functions of important organs, and with serious disturbance of the general health. In many instances they endanger the life of the patient. The danger of abscesses depends upon a variety of circumstances.

I. Their size. A very large abscess is dangerous, on account of the large amount of irritation which attends its formation, of the exhaustion occasioned by the profuse discharge, and of the tax upon the vital powers resulting from the extensive destruction of tissues.

II. Their number. Very numerous small abscesses are attended with great irritation, and lead to exhaustion of the vital powers. This is illustrated by the irritation and exhaustion attending a severe attack of small-pox.

III. Their situation. When an abscess is situated in a vital organ, it greatly embarrasses the function of the organ in which it is located, and produces a corresponding amount of constitutional disturbance. When it is so situated as to interfere with the ingress or egress of the contents of a mucous canal, the degree of danger will be in proportion to the importance of the function which it impedes. If it encroach upon the respiratory tube, it will give rise to urgent and distressing dyspnœa, bringing the life of the patient into the most imminent peril. This source of danger is illustrated by retro-pharyngeal abscesses, by cynanche cellularis, and by purulent collections in the walls of the larynx or trachea. An abscess pressing upon the œsophagus may so interfere with the function of deglutition as to expose the patient to the danger of death by inanition. A fatal case of this kind occurred under my observation a number of years since. An obstinate obstruction of the œsophagus near its entrance into the stomach, rendered deglutition impossible, and a short time before the death of the patient, there was a copious discharge of pus, which was regurgitated from the œsophagus through the mouth.

An abscess compressing a portion of the intestinal canal may occasion fatal obstrucion of the bowels. And, in like manner, an abscess in the vicinity of the urethra may give rise to retention of urine, and if relief be not speedily afforded, a fatal event may follow. When an abscess is so situated that its progress towards the surface is greatly impeded by the extreme density of the

tissues which cover it, as where it occurs beneath a fibrous membrane, its progress is attended with great pain and constitutional disturbance. In such cases, the integrity of the organ involved in the disease is threatened, and even the life of the patient may be imperilled.

IV. The state of the general health. When an abscess occurs in a person whose general health was previously impaired by great privations, or by severe illness, or by vicious habits, the danger is greatly increased by the unfavorable condition so induced. Under such circumstances, the walls of the abscess sometimes present a gangrenous character.

V. The existence of a persistent source of irritation, counteracting the reparative efforts of the system. This source of embarrassment and of danger is represented by the presence of foreign bodies, of diseased bone, and of dead tissues.

VI. An impure state of the atmosphere in the place where the patient is treated, as in the wards of a crowded or ill-ventilated hospital, in the filthy habitations of the poor, etc.

Abscesses are divided into two classes, viz. acute and chronic. An acute abscess is one which passes rapidly through its several stages, the reparative process often being completed within three weeks from the commencement of the disease. Its formation is attended with active inflammation, with severe pains, and burning heat and throbbing, and with more or less febrile excitement. When the matter has been evacuated, the inflammatory symptoms rapidly subside, and the process of reparation is speedily completed.

A chronic abscess is lingering in its progress, and almost indefinite in its duration, continuing for months, or even for years. It is for the most part attended with little or no pain, the temperature of the part is scarcely elevated above the normal standard, and there is often no febrile disturbance. When fever exists, it is apt to present the hectic type. After the matter has been evacuated, there is often little or no tendency to reparative action, the cavity, in some cases, remaining undiminished in size, giving rise to a profuse and long-continued purulent discharge; and, in other cases, contracting to a sinus or fistula, which is strongly indisposed to heal. It often occurs, after the opening of a chronic abscess, that the matter contained in it undergoes a chemical change, by which it becomes acrid and irritating, contaminating the blood, and giving rise to irritative fever, by which the life of the patient is imperilled. Chronic abscesses are often attended with a diseased condition of the bones and articulations, or with the presence of foreign bodies, which keep up persistent irritation.

In the treatment of acute abscess, in its early stage, the aim of the practitioner should be to moderate the force of the existing inflammation. The means employed for this purpose will vary according to the constitutional condition of the patient, and the activity of the inflammatory disease. When the inflammation is active, with a firm resisting pulse, and well-marked inflammatory fever, and when the patient is young and has a vigorous constitution, general or local bloodletting, purging, antimonials, and other depressing agents may be resorted to. When the patient is old, feeble, or of broken-down constitution, a supporting treatment will be indicated.

During the forming stage of abscess, warm fomentations or emollient cataplasms may be applied with advantage. These applications relieve in some degree the sufferings of the patient, and they favor the approach of matter to the surface of the body. It is desirable, in general, during the progress of an acute abscess, that the patient should abstain from active exercise. In most cases, the horizontal posture should be maintained. When suppuration has occurred to such a degree that fluctuation is distinctly perceptible, an opening should be made for the evacuation of the matter. In many instances, the patient has an instinctive aversion to the use of cutting instruments, and strongly objects to the opening of the abscess. It becomes then an important question to decide whether the objections of the patient shall be positively overruled, and an artificial opening shall be made, or whether the opening of the abscess shall be left to the more tardy operation of nature. When the abscess is of moderate size, and involves only the skin and the subcutaneous cellular tissue, it may be safely left to itself. A spontaneous cure will ultimately take place, and the only bad consequence will be that the patient will suffer more pain than he would have done, if an artificial opening had been made. But there are many circumstances under which it is the imperative duty of the medical attendant to insist peremptorily on incising the wall of the abscess, and evacuating its contents at an early period. The early opening of an abscess should always be resorted to when the swelling embarrasses an important function, especially the function of a vital organ. When an abscess, for example, occupies the posterior wall of the pharynx, and encroaches upon the entrance of the larynx, so as to embarrass respiration, no time should be lost in making a free incision, and giving issue to the matter. The same remark applies to collections of purulent matter by the side of the larynx or trachea, or pressing upon the œsophagus. In that formidable disease, cynanche cellularis, in which the cellular tissue of the neck is inflamed, and suppuration is threatened, the patient should be watched with the utmost care, as it is uncertain at what point fluctuation may first be detected, within the buccal cavity, in the fauces, or beneath the base of the jaw, and an incision should be made at the earliest practicable period, to guard against the danger of suffocation.

When an abscess obstructs the urethra, the rectum, or any portion of the intestinal canal, it is important that an early opening should be made to evacuate the matter, and to relieve the obstruction.

Abscesses in the immediate vicinity of the thoracic or peritoneal cavities, or of the articulations, should always be promptly opened, as there is great danger of the extension of inflammation to the serous or synovial membranes, or of the bursting of the abscess into the adjacent cavities.

Abscesses encroaching upon the eye, the ear, or any other important and sensitive organ, should be opened at an early period, for the relief of the intense pain to which they give rise, and for the preservation of the important function whose integrity is jeoparded. An intra-orbital abscess is not only excessively painful, but it subjects the patient to imminent danger of loss of vision. The safety of the patient depends on the early evacuation of the contents of the abscess. In like manner, the small abscesses which occur in the walls of the meatus auditorius externus, near the bottom of the concha, give rise to the most agonizing pain, which can only be relieved by a free incision. This incision should be made very early, even before the pus is fully elaborated. It sometimes happens that two abscesses occur in the same ear, and that the deeper one is concealed from view by that which is more superficial. A few years ago, I was called one evening to see two patients in one house, a gentleman and a lady, who, by a curious coincidence, were both suffering from abscess of the external meatus. I made an incision into the abscess in the gentleman's ear, and he told me afterwards that he felt strongly inclined to knock me down, the pain

of the incision being of so excruciating a character. But in a few moments complete relief followed. I made a similar incision into the abscess in the lady's ear, and, to my surprise, little or no relief was afforded. I was obliged to make a free use of anodynes to diminish the intensity of the pain. I at once expressed the opinion that there was a deeper abscess which could not then be brought into view. This opinion was verified in the course of two or three days, when the swelling occasioned by the superficial abscess had subsided.

When an abscess occurs at a great depth from the surface, when it occurs beneath a muscle, or a fibrous membrane, or other dense and resisting tissues, it is very important not only that an early opening should be made, but that the incision should be sufficiently free to give a ready outlet to the matter, and fully to relieve the tension of the inflamed parts. It is not uncommon to meet with deep collections of purulent matter, in front of the tragus, over the temporo-maxillary articulation, or behind the concha in the mastoid region, constituting what have been termed pre-auricular or post-auricular abscesses. These purulent collections are attended with agonizing pain, and with great constitutional disturbance, and they not only threaten the integrity of the organ of hearing, but they bring the life of the patient into jeopardy. A free and deep incision is the sheet-anchor of safety to the patient.

When an abscess involves a secreting gland, as the mammary, parotid, etc., the early evacuation of the matter is important, as the most efficient means, not only of relieving pain and constitutional irritation, but of preventing extensive disorganization of the glandular substance.

In all cases in which the progress of an abscess gives rise to severe pain, or to great constitutional disturbance, an incision for the evacuation of the matter constitutes the most prompt and available means of relief.

When an abscess presents a gangrenous character, being attended with rapid disintegration of tissues, and emitting an offensive odor, a free incision is important to the safety of the patient. If it be omitted, there is reason to apprehend extensive destruction of the adjacent tissues, and contamination of the blood by the noxious fluids contained within the abscess.

The manner of opening an acute abscess varies somewhat according to its situation, its depth, and the density of the investing tissues. Under ordinary circumstances, when the walls of an abscess are of moderate thickness and density, the most convenient method is to insert the point of a sharp bistoury into the cavity of the abscess, and to bring it out through the skin at the distance of half an inch, an inch, or more, from the point of entrance, and to complete the incision by carrying the knife onward in the same direction. The point selected for opening the abscess should be where fluctuation is most distinct, or at a point where, in the ordinary position of the patient, the matter will be most readily drained off. In the case of a large abscess, it will be often necessary to make one or more counter-openings at convenient points, to secure a more effectual drainage of the matter. These counter-openings may be made after the lapse of variable intervals of time, as the necessity for them may become manifest. The best point for making the counter-opening may be determined by introducing a long probe through the original opening, until it approaches the surface at a depending part of the abscess. After the opening has been made, it will often be advisable to insert a tent of lint, which may be left in place for several days, until the opening has become established. When an abscess is quite deep, and when its walls are of considerable density, it may be difficult to transfix the cavity so as to bring out the point of the knife. In such cases, after the bistoury has entered the cavity, the opening may be enlarged by raising the heel of the instrument, and ripping up the integument. When the opening is made in this manner, it is more painful than by the former method. When an abscess is confined by a very dense fibrous membrane, it may be opened by making a free incision with a scalpel directly upon its face. In certain obscure abscesses in the posterior wall of the abdomen, it will be advisable to make a cautious dissection, layer by layer, down to a point where fluctuation can be detected, in the manner recommended by Prof. Willard Parker.

When a deep-seated abscess is covered by an expansion of muscular fibres, the incision by which the abscess is opened should cross the direction of the fibres of the muscle; otherwise the purulent matter will not escape. If the opening be of insufficient size, and there be any good reason why it should not be enlarged, the escape of matter may be facilitated by the introduction of a canula. After the opening of an acute abscess, it is not generally advisable to make pressure to accelerate the flow of the matter. If the opening be sufficiently free, the matter will escape as rapidly as the walls of the cavity will accommodate themselves to the diminished quantity of its contents. Pressure will occasion unnecessary pain, and when the pressure is removed, the walls of the cavity will expand, and air will be forced in by atmospheric pressure: the air so introduced will act chemically on the matter as it is secreted, causing it to assume an acrid and irritating character.

For two or three days after the opening of an acute abscess, emollient poultices may generally be applied with advantage. But the long continuance of such applications has a tendency to increase and to prolong the suppuration, and to retard the healing process. As soon as the inflammation has lost its active character, a pledget of lint spread with cerate or basilicon ointment may be laid over the opening; over this may be placed a linen or muslin compress, to be kept in place by a roller bandage applied with a moderate degree of firmness. The dressings should be renewed once or twice a day, according to the quantity of the discharge. When there is copious suppuration, the strength of the patient should be maintained by generous diet, and, if necessary, by tonics and stimulants.

The treatment of chronic abscesses differs, in many respects, from that of acute abscesses. The constitutional treatment is mainly directed to invigorate the general health, to promote healthy secretions, and to restore to their normal condition any functions which may be disordered. When the local inflammation attending the formation of the abscess is somewhat active in its character, moderate local depletion will often be of service. Revulsion by the skin, or by the alimentary canal, will also, in many cases, exert a beneficial influence. Small chronic abscesses about the neck or face of a young female should be carefully treated with reference to the avoidance of an unseemly cicatrix. The incision should be small, and should correspond in direction with the natural folds of the skin. Gentle pressure should be made to force out the contents of the cavity. This is especially necessary in scrofulous abscesses, in which the matter contained is like a mixture of curds and whey. After the abscess has been evacuated, a compress of lint should be laid over it, and should be kept in place by strips of adhesive plaster.

Large chronic abscesses, like those which so frequently originate in the region of the psoas muscle, require to be treated with great caution, as they ex-

pose the life of the patient to imminent danger. The question has often been discussed, and it has given rise to no little anxiety in the minds of surgeons, whether these abscesses should be evacuated by art, or whether the opening should be left to nature. When the opening has occurred, whether it has taken place spontaneously, or has been the result of artificial interference, there is often a decided aggravation of the constitutional symptoms. Irritative fever, with anorexia and nausea, and great prostration of the vital powers, are very apt to ensue. The liability to the occurrence of these symptoms has produced in the minds of many surgeons a reluctance to make an artificial opening. I am myself inclined to the opinion, that in most of these cases it is best for the patient that the surgeon should make a puncture or incision for the evacuation of the matter. It should not in ordinary cases be made until the matter has approached sufficiently near to the surface to produce distinct fluctuation. It may then be expedient, when the abscess is very large, and the vital powers have begun to flag, to make a small puncture, and to allow half or two-thirds of the contents of the abscess to escape without external pressure; and then to cover the wound with adhesive plaster, and apply a compress and bandage. After a week or two, another puncture may be made, and the rest of the matter evacuated, after which a compress and bandage may be applied as before. When the abscess is of moderate size, and when the general health of the patient has not been much impaired, a more free opening may be made at once, and the whole contents of the abscess evacuated. In either case, if the pus assume an offensive and acrid character, and there be symptoms of irritative fever, a very free incision should be made, and the cavity of the abscess should be thoroughly cleansed, by injecting it with Castile soap and water by means of Davidson's syringe or some other suitable instrument. This injection should be repeated once a day, or oftener if necessary. A compress and bandage should then be applied to keep the walls of the abscess as nearly as possible in contact. The strength of the patient should be maintained by appropriate diet, with the judicious use of tonics and stimulants. When the cavity of the abscess has contracted to the dimensions of a sinus, stimulating injections may be often used with advantage. For this purpose, the surgeon may use the liquor sodæ chlorinatæ, diluted with eight parts of water, or sulphate of copper, three to five grains to the ounce, or sulphate of zinc of the same strength. These injections may be repeated daily, or at intervals of two or three days. When chronic abscesses have remained very long unhealed, it will be well to examine if there be dead bone, or some foreign body keeping up the irritation. The removal of such foreign material will often be followed by the speedy closure of the abscess. When there is no such cause of irritation, the application of a large blister over the surface will sometimes lead to a very favorable change. I have recently used this remedy in an exceedingly obstinate case, with most signal advantage.

LUNATIC ASYLUM FOR CONNECTICUT.—The new lunatic asylum for the State of Connecticut now established at Middletown, has been donated 230 acres by the State and city authorities for the purpose.

THEODORE RUETE, Professor of Ophthalmology in Leipsic, died in that city from apoplexy on the 23d of June. He was 57 years old; had held his position in the Leipsic University for five years. He was the well-known author of a text-book on ophthalmology.

Progress of Medical Science.

NEW METHOD OF TREATING YELLOW FEVER.—Dr. Alexander Fiddes, F.R.C.S.E., of Jamaica, W. I., professes to have saved more than the usual number of patients afflicted with yellow fever, by the following method of treatment: He administers at the beginning of the disease a full dose of castor-oil, carefully discarding calomel and quinine, as not only useless but injurious; this he follows up with the alkaline sulphites, giving the preference to the bisulphite of soda as being tasteless, and not likely to offend the stomach. The dose of this agent as employed by Dr. Fiddes, is twenty grains every two or three hours in a glass of water. As adjuvants, he uses iced sheets to envelop the body when the skin is hot and dry, or an occasional vapor-bath when the surface is dry merely without being hot.

SULPHITE OF SODA IN THE TREATMENT OF ERYSIPELAS.—Dr. Addinell Hewson says he has obtained results from the use of sulphite of soda in the local treatment of erysipelas, which have been to him both interesting and surprising. In extensive trial of the remedy, both in hospital and private practice, he has never seen it fail, when thoroughly applied before the deep planes of cellular tissue had been invaded by the disease. Before such parts had become affected, a solution of ten grains of this salt to the ounce of water, when thoroughly applied on lint all over the surface affected, and to a considerable distance beyond it, and covered with oiled silk to prevent the evaporation of the solution, had not only produced a decided bleaching effect on the discolored surface in every such instance, in the first twenty-four hours of its use, but had invariably destroyed all traces of the disease in forty-eight hours from its first application. The effect was the same, whether the application was made in the traumatic or idiopathic form of the disease. He has thus cured twenty-seven cases, seven of which were of idiopathic erysipelas. Even in the cases where the deep planes of cellular tissue were involved, as well as the surface, the disease on the surface was always apparently affected by the application. It was most positively bleached in all instances, and in many was evidently destroyed, within the period above stated, even while that in the deeper part proceeded to suppuration.—*Trans. Col. Phys., Philadelphia.*

MENORRHAGIA AND MENORRHAGIC PAIN TREATED SUCCESSFULLY BY THE SPINAL APPLICATION OF HOT WATER.—Dr. John Chapman, in the *Medical Mirror*, speaks of the local application of hot water in relieving the distress of menorrhagia. He reports a case in which water, heated to 120° F., was applied along the lower third of the spine, and kept there until the water became cooled. The result of the first application was a wonderfully rapid and great relief to the patient's back, and the flow was to a great extent restrained. The flow had quite ceased, after seven applications of the water, at the end of the fifth day, and had been so lessened in quantity, that but little more blood was lost during the four days after the treatment began than was lost during the previous eighteen hours. Moreover, the patient found herself very much better and stronger than during her previous periods. Dr. Chapman highly recommends this treatment.

PREVENTION OF PURULENT ABSORPTION BY ERGOTINE.—It appears, from the observations of M. Labat, a physician of Bordeaux, that the administration of ergotine after amputation is attended with the most beneficial results. The ergotine is given after the amputation,

and each day up to the day when the ligatures come away, the medium dose being from five to six grains. M. Labat's memoir on the subject, presented to the Societé de Chirurgie, records fourteen cases treated in this way.—*Medical Times and Gazette.*

Amblyopia Produced by Tobacco-Smoking.—M. Viordin has reported three cases of ambiyopia caused by smoking. In the treatment of these cases the quantity of tobacco smoked wes reduced, under the direction of M. Viordin, and the sight was restored in the course of a few weeks.—*Medical Times and Gazette.*

Chorea Treated by Richardson's Apparatus.—An interesting case in which chorea was successfully treated by freezing the skin over the spinal cord has lately been recorded in the *Gazette Hebdomadaire*, and tends to some extent to support the ice theory of Dr. Chapman. A little girl, about seven years old, was attacked with chorea, and presented herself to Dr. Lubelski, who, having tried in vain the usual tonic and antispasmodic remedies, determined to produce anæsthesia of the spinal cord, by means of ether spray. The instrument used was the variety of Richardson's apparatus used by dentists, and which has a double nozzle. It was applied to both sides of the spinal cord, and the ether spray was forced upon the surface for three or four minutes, the operation being twice repeated. The result was that all the abnormal movements ceased, and the natural powers of motion were restored.—*Lancet.*

Common Salt for Wounds.—A French writer speaks in terms of the highest commendation of chloride of sodium in the treatment of wounds and ulcers. The first effect on a fœtid wound he says is to destroy the odor immediately. Another immediate phenomenon observed is the pinkish hue which it gives the decomposed sanguineous, blackish liquids in the wound. At the same time there is felt a peculiar sensation of cold and prickling, which may even become slightly painful. The suppuration diminishes rapidly, and in the changes in it has a happy effect on the system, the appetite improving and the strength returning. Four hundred cases of wounds thus treated are reported. There was neither erysipelas, nor tetanus, nor hospital gangrene in any one, though the hygienic condition of the hospital was bad. In only one case was there pyæmia. The solution first applied was in the strength of one drachm to a pint of water. After using this a few days, a concentrated solution was employed. In fistulous cases the solution was injected into the sinuses.—*Pacific Medical and Surgical Journal.*

Pompeii.—One of the latest discoveries reported from the excavations, is that of a bronze vase hermetically sealed, and containing a considerable quantity of water, which was pronounced clear, fresh, and remarkably soft after its repose of 1800 years.—*Richmond Med. Journal.*

Lime Inhalations in Pseudo-Membranous Croup.—Dr. B. B. Wilson, in the *Medical and Surgical Reporter*, speaks very highly of lime inhalations, and gives some instances in which the curative effect of the remedy was most marked and decided. Owing to the difficulty in inducing children to use the inhaler, he "frequently extemporizes a vapor-bath, by throwing a large blanket over the child's head and shoulders, as well as over the sofa upon which it reclined, and including also within its circumference a pitcher, in which a small lump of quicklime was being rapidly slaked by means of boiling water. In this way the air surrounding the child's body, as well as that respired, was highly charged with the vapor of lime-water. This process was repeated every hour, or every half hour, when the breathing seemed more than usually hurried and difficult. The immediate effect upon the patient seemed to be soothing, the most urgent dyspnœa being relieved, and the little sufferer almost always becoming quieter and falling into a light sleep under its use."

Nasal Hæmorrhage.—Dr. Heard, in the *Gazette des Hôpitaux*, says he never fails to stop the most obstinate epistaxis by a simple process of compression of the nostrils. Being subject in early life to epistaxis, he found the hæmorrhage come from a part of the septum within reach of the ends of the fingers. By compressing the alæ upon the septum, the bleeding generally ceased within five minutes. Even the hæmorrhages of typhoid fever, or those occurring with organic disease of the heart, have been usually checked without losing a teaspoonful of blood.—*Boston Med. and Surgical Journal.*

Causes of Deaf-Dumbness.—Dr. Peet, Principal of the New York Institution for the Instruction of the Deaf and Dumb, has recently published statistics from which he deduces the striking conclusion that in Europe, generally, the chances of the birth of a deaf-mute child are more than twice as great as in the United States, or 615 in a million there, against 278 in a million here; while the chances of the loss of hearing after birth are in Europe, except in Germany, much less than in the United States, to wit, 154 in a million there, and 222 in a million here. Such statistical results as these form the data from which we must study the cause of deaf-dumbness. The striking contrast between the Old World and the New may be owing, in part, to climate; in part to the severe out-door labors imposed on women of the laboring classes in many countries of Europe; in part to idiosyncrasies of race. The European returns which show such a preponderance of congenital cases, are chiefly from countries where the bulk of the population is of the Celtic and Latin races. We have very few such returns from European populations of the Anglo-Saxon and Teutonic races, and most of those we have agree with the American returns in presenting a large proportion of accidental cases. The causes of congenital deafness are as yet but very imperfectly understood. When deafness is the apparent result of a known disease, or accident, it is comparatively easy to judge with probability of the mode of operation; but in most cases of congenital deafness we are left wholly in the dark, even as to the condition of the organs of hearing. They are too deeply seated for more than a very superficial examination in life, and opportunities for dissection of subjects known to have been deaf-mutes rarely occur.

The remote causes that have been, with most probability, assigned for congenital deaf-dumbness are the following:

1. Unequal ages of the parents, especially where the mother is older than the father, or advanced age of either parent, especially of the mother.
2. Ill health and feebleness of constitution in one or both parents, especially where there is a hereditary tendency to scrofula.
3. Impairment of the procreative power, especially in the father, through early dissipation or bad habits.
4. Intermarriages of blood relations.
5. Causes operating during gestation, through the excited imagination or nervous sensibility of the mother.
6. Ill health of the mother during gestation, or physical accident during that period.
7. Intemperance in one or both parents about the time of conception.
8. The influence of unhealthy occupations, bad wa-

ter, inferior diet, or damp dwellings of the parents, on their offspring.

9. Direct hereditary transmission.

All these primary causes, it will be seen are, *mutatis mutandis*, as applicable to other congenital infirmities as to deaf-dumbness. A defective bridge gives way at its weakest point; and where there is no specially weak point, the point of fracture may be determined by slight causes. So it seems there are families in which the weak point of the constitution is the apparatus of hearing; but in many cases the tendency to deafness, rather than to idiocy, blindness, lameness, or some other infirmity, was biassed by causes that often baffle research, because they seem so slight that they elude attention.

Phthisis in Barbadoes.—Phthisis is a disease that has been supposed hardly to exist in the tropics, but observations of late years seem to say that such is far from being the case. In the island of Barbadoes it is much more common than formerly, and quite so amongst the negroes. Since the abolition of slavery, the diet of the blacks has probably been less nutritious than when they were not obliged to provide for themselves, consisting now chiefly of Indian-meal, sweet potatoes, and flying-fish—which last delicious fish is taken in immense numbers around the island; and to this cause the increase of disease seems to be attributed, though the general appearance of the blacks struck me as quite healthy. And I would remark that the number of mulattoes, in whom we generally find a greater tendency to tubercular affections than in the pure negroes, appeared to me to be small. I saw several cases of phthisis at the hospital, and was told that when patients come to the island with this disease no marked benefit is experienced, though the climate, if a tropical one could have any effect, seems to be all that could be desired. Scrofulous glands and disease of the joints are also common, but tubercular meningitis is very rare.—Dr. J. B. S. Jackson, *Boston Med. and Surg. Jour.*

Burns or Scalds.—The following is one of the best applications we know of in cases of burns or scalds, more especially where a large surface is denuded of the cuticle:—Take a drachm of finely powdered alum, and mix thoroughly with the white of two eggs and one teacupful of fresh lard; spread on a cloth, and apply to the parts burned. It gives almost instant relief from pain, and, by excluding the air, prevents excessive inflammatory action. The application should be changed at least once a day.—*St. Louis Med. Reporter.*

Monthly Period of Infecundity.—Dr. Avrard, a physician of Rochelle, has published a work entitled "Generation and the Duration of Pregnancy in the Human Race," in which he has arrived at the following conclusions:—1. The cycle of generative functions lasts 28 days. It is divided into three periods of unequal length, which the author calls *menorrhagic*, *generative*, and *hypnotic*. 2. Menstruation returns normally every 28 days, starting from the accession of the courses. Its duration is indefinite. 3. A certain time elapses, most frequently, and perhaps always, between the end of the courses and the beginning of the generative period; this time the author calls the *interperiodic phase*. 4. The generative period always ends the 14th day after the beginning of the courses. 5. It has been shown by an observation of fifteen years, and resting to-day upon thousands of facts, with proof and counter-proof, that woman is physiologically barren during fourteen days in twenty-eight—that is to say, after the fourteenth day, commencing with the appearance of the courses, till the end of the following period. M. Avrard does not admit the possibility of impregnation during the period of the menses, and maintains that parturition is effected always two hundred and seventy days after impregnation.—*Jour. de Méd. et de Chir. New Orleans Med. and Surg. Journal.*

A Case of Dislocation of Femur.—Dr. G. W. Topping, of Dewitt, sends to the *Review* the account of a case of "probable dislocation of the head of the femur into the great sciatic notch, and reduction by manipulation before the diagnosis had been satisfactorily established." A boy had fallen from a sleigh, had been caught by the right foot, and dragged for a considerable distance on the ground. A superficial examination revealed symptoms of dislocation of right femur, upward and backward. He was unable to stand upon his right foot, or move it outward or forward. Standing upon the left foot, the right great toe rested on the left os calcis. The right heel was lifted slightly from the floor, and the corresponding thigh closely hugged its neighbor. The boy referred the pain to a point below the knee, and the doctor flexed the thigh upon the body at a right angle. Taking hold of the knee with one hand, and the ankle with the other, he then rotated the limb outward. The patient complained but little during this process, and no sudden snap indicated the reduction of the dislocation; but all symptoms of injury, except a slight stiffness of the muscles, suddenly vanished, and the boy, who a moment before was not able to bear his weight on the limb, could now walk without difficulty. Dr. Topping considers the lesion to have been a dislocation of the head of the femur into the great sciatic notch.—*Detroit Rev. of Med. and Pharmacy.*

Case of Bromine Poisoning.—Samuel P. Duffield, Ph. D., in the *Detroit Review of Medicine and Pharmacy*, gives the following successful treatment of poisoning by bromine inhalation. The corrosive action of the bromine was such that the glottis had closed with a spasm, and did not yield willingly. The patient was brought near to a steam-pipe, the mouth held open, and the steam thrown from some distance, so as not to burn him, into his mouth and over the face. It had the desired effect, and the patient was subsequently sent home. The steam inhalations were continued for some time, and the patient recovered. The attention of the profession is particularly called to the great value of steam inhalations in cases of poisoning by corrosive vapors.

Occlusion of the Os Uteri.—Mr. Mellor read notes before the Manchester Medical Society, of a case of occlusion of the os uteri during labor. The patient, aged 21, was a primipara, and was at her full time. On his arrival, there were no urgent symptoms, and he left again shortly. He was soon sent for hurriedly. Severe expulsive pains had been going on for some time. The external organs were in a state of relaxation, and delivery seemed at hand. But, on examination, not a trace of the cervix nor of the os could be detected. The posterior wall of the vagina and the cervix were quite continuous with each other; as if agglutinated together. A careful examination was then made with a speculum, but nothing like the os could be seen. Mr. Robertson also saw the case; and it was determined to make an opening into the uterus. This was done in the presumable site of the os with a scalpel; and, after a while, as no dilatation took place, a curved bistoury was inserted, and the incision was prolonged anteriorly and posteriorly. A great quantity of meconium escaped. The occiput speedily came through, and all went on well. The labor lasted six hours, and the recovery was uninterrupted. There had previously not been a

trace of uterine affection, and menstruation was always healthily performed. Dr. Thorburn made some remarks on such cases, and quoted Mattei, who had reported forty-two cases, not all primiparæ, and who considered that, in the majority, the occlusion was owing to simple organization of the cervical plug of lymph, and not to inflammation.—*British Med. Jour.*

Death from Swallowing two Ounces of Chloroform.—Dr. D W. Stormont, of Topeka, Kansas, reports (*Leavenworth Medical Herald*) a case of suicide by the internal administration of chloroform. The patient was twenty-six years of age and in good health at the time. He swallowed two ounces of undiluted chloroform at a single draught. In three minutes after he had laid himself composedly down, he could with difficulty be aroused from the stupor into which he was rapidly sinking; and though he could not speak, he indicated that he had severe pain in the region of the stomach. In five minutes he was entirely unconscious and breathing stertorously. He died in just one hour after taking the draught. Medical assistance from some cause did not arrive until a few minutes before he died, and nothing was done to counteract the effects of the poison. At the post-mortem examination, the surface generally was livid; the face, neck, chest, and nails very much so. Bloody froth was issuing from the mouth and nostrils. On opening the chest, both lungs were found to be dark externally, and fully distended. They were uniformly congested with dark, liquid blood, and the posterior portions were perfectly engorged with it. Both sides of the heart were nearly full of black, uncoagulated blood; the liver and spleen both normal externally, but somewhat softened, and filled with dark, liquid blood. The œsophagus was congested. The stomach, at the cardiac end, and along the greater curvature, and half way up each side, was discolored externally, dotted over with ecchymosed-looking patches, giving it a mottled appearance. It contained two or three ounces of a light-colored liquid, which had a slight odor of chloroform. At the cardiac end, internally, and along the bottom nearly to the pyloric end, the mucous membrane was of a dark-red color, softened, and easily peeled off with the thumb-nail. Up the sides it was of a brighter red, speckled appearance, and not softened. The intestines were healthy. Circumstances prevented the extension of the examination, which is much to be regretted. The reporter of the case closes with the following remarks:—"Recoveries are recorded from drinking two ounces, or even more, of chloroform, but active measures were used—as the stomach-pump, emetics, stimulants, internal and external artificial respiration, galvanism, etc. As an internal stimulant, the spirits of ammonia, or the carbonate of ammonia, is the best. Very dangerous symptoms have been produced by half an ounce, and death has been caused by one ounce. Dr. Stillé says: 'When death has been produced by the internal use of chloroform, its local irritant action has evidently been the chief cause of the fatal result.' In this case, death followed too soon to have been produced in this way. It was more probably caused by the action of the poison on the blood and the cerebro-spinal system, as in prolonged inhalation of the vapor. A peculiarity of this case is the shortness of the time between taking the chloroform and death, as compared with other fatal cases reported."

Sloughing produced by Local Anæsthesia.—We examined, a few days since, in the Middlesex Hospital, a young woman whose case is of no little importance in reference to the question of local as against general anæsthesia for operations. Mr. Lawson had diagnosed the existence of an abscess behind the patient's breast, and as the pus was very deep (under the pectoral muscle), the refrigerator was used, paraffine ether being employed. Congelation was rapidly produced, and kept up for a few minutes. The result has been, that a portion of skin, about an inch by three-quarters of an inch, over the upper part of the breast, had sloughed, and its healing will necessarily be attended by an unseemly scar. The patient is a maid-servant; were she unfortunately a lady, the undress of the modern ball-room would be impracticable without revealing such a blemish as might seriously damage her value in the matrimonial market. The case is certainly exceptional; but the circumstance is worth remembering when exposed parts of the body are to be operated upon.—*Lancet.*

New Mode of Treating Fracture of Lower Jaw.—Dr. Benj. H. Riggs, of Selma, Ala., reports in the *Southern Journal of Medical Sciences* for May, 1867, a case of compound fracture of the inferior maxilla, occurring in an adult, in the treatment of which he claims that he made use of a new method. The point of fracture was "immediately to the right of the symphysis, and through the socket of the right central incisor, the outer half of that tooth being exposed to view; the right fragment was very much drawn inwards; the gum was freely severed at the seat of fracture." A pasteboard splint and Barton's bandage was first applied, and the patient put upon his good behavior. This method proved unsuccessful, for the patient took the liberty of neglecting the doctor's instructions as to rest and method of eating, so that at the end of six weeks there was found a fistula under the chin, but no evidence of an attempt at union of the bones. Dr. Riggs then determined to use some mechanical appliance within the mouth, and obtained the assistance of Dr. S. G. Todd, a dentist, who took an impression in soft wax, formed from it a plaster cast, and upon this constructed a silver band, which was "made to fit every inequality of the teeth, completely encircling the first nine; it was not quite as wide as the teeth were long, and did not interfere with the closure of the mouth. An intercommunicating portion extended from the front arm of the band to the posterior, at the seat of fracture." This appliance was found to maintain exact coaptation of the bones. A tin fracture-box, which was soon discarded as cumbersome and unnecessary, and a two-tailed bandage, completed the apparatus. Under this treatment the fistula closed at once, and the case seemed to progress favorably for some weeks; but at the end of that time it was found necessary to remove the right central incisor, which, being at the seat of fracture, had acted as a foreign body. It was then seen that there had been no attempt at bone formation. The band was now shortened and readjusted, after which the fistula again closed, and the case progressed favorably to the end of the treatment. At the end of six weeks from the extraction of the tooth the apparatus was removed, and the patient discharged, although on account of the anæmic condition of his system, osseous union was not yet perfect.

Curare in Epilepsy.—Dr. Benedikt informs the Vienna Medical Society that the subcutaneous injection of curare has a favorable influence over epileptic diseases. A man, 20 years of age, had had epilepsy since he was 9 years old. During five months he was subjected to curare injections in hospital. For the last fifteen months he has had no return of the fits. Four similar cases, equally successful, were related by Dr. Benedikt. The injections were used three times a week, under the skin in the neck, an eighth of a grain being used at each operation.—*British Medical Journal.*

HOSPITAL EXPERIENCE.

THE facilities for study, experiment, and observation, afforded in connection with extensive hospital practice, are fully appreciated by medical men; as evinced not only by the laborious exertions necessarily made to obtain appointments upon the medical staffs of public institutions, but also, and perhaps in greater degree, by the tenacity with which positions are retained by the successful candidates. Too few of those who enjoy hospital privileges think of availing themselves of their superior advantages for a few years merely, and then gracefully retiring to welcome a successor. Professional pride, or professional capital, whether it take the form of fame as a teacher, or fame as a practitioner, creates a desire to make, for the time being, the most out of an appointment, and then induces a habit to hold on to it as long as possible—until infirmity suggests the policy of withdrawal, or the charms of a preferable position woo its reluctant worshipper to the embrace of a heavier responsibility.

Inseparable from the charge of a large number of sick, are duties and personal sacrifices which are arduous and onerous; the services requisite for the fulfilment of which are recompensed by no pecuniary equivalent; nevertheless, well as this is understood, new aspirants for duties and responsibilities press forward their claims to gratuitous employment, whenever there is wafted from the medical staff of a hospital the slightest suspicion of the shadow of a vacancy.

Some desire the position to be enabled to study; others require it to be enabled to teach; a few think it necessary to the establishment of their reputation or standing.

The advantages of a position in a hospital are very great.

Practical experience is necessary to success in the treatment of disease. The most brilliant theories of cure must withstand the test of bedside criticism before they can be relied upon, and this has been the case from the earliest dates of the professional record, whatever the disease, whatever the therapy; results differ from expectations so often and so constantly, that the action of new remedies cannot be depended upon, until confirmed again and again by repeated observation.

The practice of medicine, as ordinarily pursued by the family practitioner, does not often afford opportunities ample enough or precise enough for the prompt determination of the value of asserted discoveries in therapeutics; the physician who is constantly employed in the exercise of his profession, seldom has time for the systematic prosecution of his investigations, and if he has plenty of time for methodical observation, his opportunities for availing himself of it are apt to be less frequent. Then again, in private practice it is extremely difficult to control patient, nurse, attendants, medicine, diet, social intercourse, and so on, sufficiently to judge correctly of the individual influence of special modifications of treatment unaffected by interference from extraneous circumstances. Implicit compliance with all the instructions of the physician is rarely encountered in private practice; the medicine ordered for the patient may be administered with scrupulous exactitude by the conscientious nurse, but indiscretions of diet, of social intercourse, etc., are often indulged in without telling the doctor, especially in cases where danger to life has not excited the fears of the patient and his friends, to the detriment of any investigation in therapeutics by the physician. Effects are thus encountered, which may or may not be the result of the ascribed cause, and therefore, in order to estimate discerningly the value of each disturbing element, investigation is necessarily prolonged, suspended, and again renewed as opportunities offer, until sufficient evidence is collected to justify the adoption of ultimate conclusions. Thus, in important cases, experience at the bedside in private practice is accumulated slowly and with great labor.

In a well-regulated hospital—and every hospital should be well regulated—the surroundings are different; discipline is essential to the preservation of order, and patient and nurse, apothecary and cook, medicine and drink, are under the control of the physician; such food and medicine as he prescribes, and such only, is administered to the patients; no officious interference by nurse or relative is permitted or dreaded; the temperature of the ward, the degree and character of ventilation, the access of visitors to the bedside—all this is regulated in accordance with the instructions of the physician; intelligent professional assistants watch the course of the disease, note important changes and results in the absence of the principal attendant, examine the secretions and excretions, and bring into requisition all the appliances of differential diagnosis, at hand at the moment needed; observations are made at stated intervals, and recorded for the examination of the principal; fact is accumulated after fact, until, eventually at the close of the case, a distinct and complete record has been made of all important features, with due allowance for every disturbing element in its management. The simultaneous presence of a number

of similar cases, as often occurs in the wards of a large establishment, offer facilities for bedside comparison which cannot be made where patients reside apart, and which are invaluable in the study of the progress of disease and its cure. And at the fatal termination of an obscure or severe case, the opportunity for post-mortem examination under the most favorable circumstances, as to time of day, and conveniences of a special apartment for that purpose, are of the utmost utility; careful drawings can be made of morbid appearances, for future study and reference, specimens preserved for minute examination and comparison, etc., etc.

Thus in hospital practice tolerably reliable results can almost always be secured as to the history of disease or the effect of treatment. Observation alone, however, is but of limited benefit; the advantage is confined to the observer and those with whom he is in immediate professional intercourse, and to the observer himself it is of but limited advantage unless the observations made are recorded at the time of occurrence. Facts are to be accumulated at the bedside; they are to be considered, pondered on, collated, and compared with facts previously accumulated in the study. The conclusions of one who adopts this plan will be far different from what he would arrive at from dependence upon memory alone, for it has been acknowledged by writers that the impressions made upon the mind by recollections of experience do not always confirm the recorded results of statistics.

Hence the importance, in hospital practice, of carefully recording experience which is new, or which will bear upon doubtful or disputed points in medicine; but such records should not remain buried in the case-book of the hospital, or the professional note-book of the physician; they should be announced for the benefit of those who have not access to the wards of a hospital, and who in great measure depend upon hospital men to verify assertions and determine mooted points in therapeutics. The members of a hospital medical staff are looked upon, by the rank and file of the profession, as leaders in the investigation of disease, therapy, and pathology, and it is a duty they owe to their less prominent brethren to tell them what they have learned, or what they have discovered in their hospital experience.

Abroad, it has been customary for the staff of a hospital to publish its hospital reports periodically, comprised of papers on special subjects of interest, carefully prepared, incorporating the results of their observation and experience, with the collated record of the sentiments and conclusions of others in this country. The coming year will inaugurate a similar system in two of our most prominent hospitals—Bellevue Hospital, of New York, and Pennsylvania Hospital, of Philadelphia, establishments which present as good material in character of cases, and acquirements of attendants, for valuable papers as any similar establishments elsewhere. In calling attention to this important and praiseworthy movement, we would urge the adoption of a similar plan upon every hospital staff in the country. To such we would say, publish whatever occurs of interest or instruction in the institutions under your charge, whether it form a thin pamphlet or a bulky volume; if you cannot find a publisher with sufficient enterprise to print it, ask the institution receiving the benefit of your gratuitous services, to acknowledge their obligation to the profession by the periodical appropriation of a sum sufficient to cover the expense of publication. We need in this country more new works, practical, suited to the climate, the people, and the style of practice. Clinical reports of hospitals are always welcomed; they present in succinct form the views and results of the day; they are passing events, and are always welcomed, and therefore they form a prominent portion of the contents of our medical journals. Summaries of sets of cases treated alike, or treated differently, collected with care, will doubtless prove equally acceptable in the form of yearly Hospital Reports, and we anticipate that the annuals of Bellevue and of Pennsylvania Hospital, will meet with a cordial reception from the profession at large, not the less agreeable because it will be a new form of medical literature.

Inestimable, however, as are the advantages of hospital experience, and much as we should value their published record, we must be careful not to over-estimate their value. Apart from the humaneness of attending upon those sick compelled in their extremity to accept the kind offices of strangers, the main object of hospital practice is to furnish general practitioners with a reliable source of estimate of the value of various therapeutic agencies offered for their adoption, that they may make use of the results in the ordinary practice of their profession. We are too apt to take these results and apply them just as they are. This is an error. In studying and comparing hospital reports, we must not forget that they are results obtained under hospital *régime*, and that they will become modified when we put them to practice. We must remember that disease is resisted with more routine in the ward of a hospital, than in the private chamber of the sick; and that there exists, too, a modifying influence in the social position and relations of the invalid at his own house, and the patient in a public institution; and in institutions altogether eleemosynary, there is a still greater difference in this respect. These, and similar considerations, modify the condition of the patient essentially, and thus both directly and indirectly influence the course of the disease and the result of therapeutic interference. Under certain circumstances, therefore, we shall anticipate the success in the treatment of certain diseases to be greater in the hospital than it will be in the private residence; and under other circumstances, the reverse will be the case. A striking example, for instance, of the great difference in the result of treatment of the same disease as it is encountered in the

hospital, and as met with in private practice, is afforded us in typhus fever. The same physician will be successful with his typhus patients in hospital at the same time that he is losing them in his private practice; and the latter class of patients will too, as a usual thing, belong to a better class of society, and yet the success of treatment will predominate with the poorer class. Why are the results not constant, even under the most favorable circumstances of worldly resources? Because in the one case we can do much to improve the hygienic condition of the patients, in providing better diet, better clothing, better air, and the system responds to the assistance; on the other hand, the private patient occupies well-ventilated apartments, lives in a healthy locality, possesses ample change of linen and bedding; is supplied with the most desirable articles of diet, and yet the means are inefficient here, which have sufficed in the hospital, because we cannot improve his hygienic condition; or, if the private patient be not of the better class, and lives in confined localities, with restricted diet, limited change of clothing, we cannot improve his hygienic condition to the same extent as if he were in hospital, and hence the success of remedial agents will, in each instance, be less certain. The same process of reasoning can be carried out in other diseases, and especially in the treatment of surgical diseases, to show that in guiding ourselves by the results of study, experiment, and observation, as recorded in hospital reports, it is necessary to exercise a certain amount of discretion in applying to private practice these results of hospital experience.

We have doleful accounts of the prevalence of the yellow fever upon our Gulf coast. In Galveston, Texas, where, according to the views of the physicians there, the disease was not introduced but germinated, the type has been particularly malignant. A despatch from this city, received by the U. S. Secretary of the Treasury during the present month, states that the fever is "fatal beyond precedent. Out of twenty-six officers connected with the Custom-House, only three are fit for duty. The remainder are either sick or dead." The victims in general are foreigners, who constitute a very important element in the population. The Commandant of the Fifth District (General Griffin) reports to his superiors under date Sept. 3, that "there is not an army surgeon in or around Galveston fit for duty, and that the regular medical practitioners of that city have more than they can possibly attend to."

The scourge appears to be still under control at Indianola, Lavacca, and Victoria—but not so at Corpus Christi or New Orleans, at which last, according to the declaration of the Health Board on the 3rd inst., it is now epidemic, but of mild type. Accounts from the West Indies are somewhat more favorable, particularly in the case of the more important towns—but from every quarter there comes the gratifying intelligence that the members of our profession are laboring manfully to stay the pestilence, in a spirit that is as self-sacrificing as it is commendable.

The cholera also seems to have gained a new impetus in certain parts of Europe. The United States Consul at Palermo, Italy, reports that "On the 31st of July, up to the time of the mailing of my last despatch, there had only taken place six or seven cases of cholera, but before the day was over they ran up to twenty-nine cases. On the 1st of August it went up suddenly to two hundred and eighty cases, and it has kept thus up to date, averaging from two hundred and fifty to three hundred cases daily. The lower classes, as usual, are the greatest sufferers; but it has, however, spread among the middle and even the upper classes. It is of a more violent and fatal nature than last fall, for hardly one-third of the attacked have so far got over it. The entire population is panic-struck; the greater part of the wealthy families have escaped to the Continent, the middle class have left the city and are staying in the villas and in the suburbs, and many of the laboring classes have gone up to the mountains and pitched tents in the open fields. The city has a very mournful aspect, and business is almost entirely suspended."

In the Calabrias, and Sicily, and a few of the northern provinces, the people add to their sufferings the dread of poison, which they believed to be administered through several malevolent agencies. Indeed, we learn from the *Gazette de France* that, "On rumors of cholera at Naples the populace rushed in a mass to the abode of a fortune-teller called the Sibyl, massacred her, and cut her into morsels."

The same paper adds in this connection: "The authorities have suspended the march of troops, fairs, and even the examination of students. At Naples all ships coming from Leghorn are placed under quarantine."

A letter from the Basilicata to the *Avenir* of Naples states "that the cholera is making terrible ravages in several communes of that province. In that of Miglionico, of which the population does not exceed five thousand souls, the number of deaths daily amounts to from fifty to sixty. Some families have been entirely destroyed." The disease has likewise appeared in Warsaw and in Danzick, and, if we credit the secular prints, "as a fearful epidemic."

In our own far west, up to the date of our present writing, the number of victims has not yet perceptibly declined—the Indian Territory, south of Kansas, having been sorely visited, and the population of Fort Gibson having lost fully thirty-seven per cent. of their whole number. From the other infected military stations we have little if any news, which we trust may be regarded as a symptom indicating a fair condition of the public health.

The coming of cool weather brings with it a disposition for renewal of work in medical circles. The different societies which have been enjoying a vacation

have resumed their sessions, and the preliminary lectures in the medical schools have been commenced. The number of medical gentlemen who have been recruiting their wasted energies upon their farms and country seats have returned with renewed vigor to practise their art, and everything points towards the possibility of a winter of more than ordinary activity in the medical line. The meetings of the societies are well attended, and an interest is manifested in their proceedings which is as gratifying as it is encouraging. The students are beginning to assemble from different quarters, and the prospects of good classes on the part of the colleges are as promising as they have been at any time heretofore.

Reviews.

A PRACTICAL GUIDE TO THE STUDY OF THE DISEASES OF THE EYE; their Medical and Surgical Treatment. By HENRY W. WILLIAMS, M.D., Ophthalmic Surgeon to the City Hospital, etc., etc. Boston: TICKNOR & FIELDS. 1867. pp. 421.

SOME time since we noticed the essay on "Recent advances in Ophthalmic Science," by this author.

The work now before us is a second edition, and contains as an appendix the essay above mentioned.

"In offering this treatise to the profession, and to those who are about to enter it, the author does not assume to set forth all which is known in respect to diseases of the eye."

The idea seems to be to give the student a general knowledge of eye diseases, "and to allow him to consult other works at his leisure, should he wish for complete information regarding them."

It does not seem to us that this is the correct aim in writing a monograph. Text-books for students on general subjects are the proper places to set forth *general* ideas of diseases. A practising physician who consults a work on a special class of diseases, expects to find in it a full account of the pathology, treatment, etc., which may be of use to him in the case that he is looking up. He does not wish "to consult other works at his leisure." Besides, we do not remember to have seen reference to a single author in the whole book, so where shall the general practitioner find, in other works, what he fails to find in this?

The great advances in ophthalmic science that have been made within the last few years, and the failure of works on practice of surgery to keep pace with this advance, do to some extent render necessary such a work as the present.

It is a very readable book, and by its perusal the physician will gain a very good idea of what can be accomplished by a skilled oculist, if he does not himself learn exactly how to treat eye diseases.

Throughout the work are various practical suggestions that are very useful, and which are original with Dr. Williams, who, besides being a careful student and compiler, has that rare qualification, in a medical man, of having an original turn of mind, which does not take all the accepted notions for granted. His modification of Bowman's probes for the treatment of lachrymal obstruction seems to be a valuable improvement. They are "made with bulbous extremities," and "with the third of the probe nearest the end much more slender than the remaining portion." They are made on the same principle as certain bougies for urethral stricture.

While speaking of the treatment of diseases of the cornea, Dr. Williams uses this expression: "If he act as a mere specialist, and attempt to gain his object by local remedies alone, his best endeavors will be baffled," etc., and "constitutional remedies are of quite as much importance as any local applications." Some oculists seem to ignore all constitutional participation when treating their eye cases. It seems to us that the use of tonic remedies, and attention to the general health, are quite as important, if not more so, than local applications, in the treatment of ulcers of the cornea, phlyctenular keratitis, etc.

And in syphilitic iritis the exclusion of preparations of mercury, and the entire reliance on atropine, seems at least injudicious. Adhesions of the pupillary margin are not the only evil results of the syphilitic poison; and the mere fact of a physician being a *specialist* gives him no right to let his patient suffer from any trouble not immediately in his line, while under his care. Therefore we think that Dr. Williams hardly puts the case strong enough when he says, "Where interstitial corneitis exists as a complication, the use of mercurials may be admissible." We should say indispensable.

The article on "inflammation of the meibomian and ciliary glands," is one of the best that we have seen on the subject. It will repay careful study. By carefully carrying out the plan of treatment here described, almost all cases of the disease in question prove curable.

The appendix would doubtless be as new to many physicians now as when it first appeared, and it is well worth a careful reading. The part on the ophthalmoscope, and the accompanying plates, give an excellent and simple explanation of that instrument and its use, as we have already noticed in our review of it, when issued as a separate work. The book as a whole is a valuable one, and creditable to its distinguished author, although we are constrained to repeat that a "guide" should be a little more minute, and a bibliography which would only take up little space, would greatly enhance its value. We commend the beautiful typography and paper and binding to the attention of the New York and Philadelphia publishers.

NOTES ON THE ORIGIN, PREVENTION, AND TREATMENT OF ASIATIC CHOLERA. By JOHN C. PETERS, M.D. 2d Edition with an Appendix. N. Y.: D. VAN NOSTRAND, 1867. 12mo., pp. 200.

THIS excellent and very readable work of Dr. Peters has advanced to a second edition, and we are pleased to notice the fact as an evidence of the appreciation with which the profession regards the labors of the author. Our readers are already acquainted with the intrinsic merits of this *brochure*, and we again take occasion to commend it to their careful perusal and study, as a work singularly complete in all those facts pertaining to cholera which the recent investigations of the ablest minds in the profession have given us.

THE MEDICAL REGISTER OF THE CITY OF NEW YORK AND VICINITY, to which is also added a nearly complete list of the members of the Medical Societies of the State of New York for the year commencing June 1, 1867. Published under the supervision of the New York Medico-Historical Society. JOHN SHRADY, M.D., Editor. New York: N. Y. PRINTING CO., 1867.

THIS very welcome annual comes to us much enlarged, compared with its predecessors, and under the charge of a new editor. Although somewhat delayed in its publication on account of the many additions which were thought necessary to be made, the profession will doubtless be unwilling to find fault with the circumstance in view of the remarkable completeness of the work. As it now stands it may be considered the per-

fection of a Register. No pains have been seemingly spared to make it in every respect a reliable book for reference on all matters pertaining to medical matters in the city of New York and vicinity. The list of practising physicians is as complete as the utmost care in canvassing the districts could possibly make it, while the office hours of all are accurately and reliably given. This latter feature alone is sufficient to recommend for the little volume a place upon the table not only of every practitioner in the city and vicinity, but of those throughout the adjoining States who may have occasion to send their patients to the city for purposes of consultation. By being reliably informed as to the time when the physician to whom his patient is to be sent can be found in his office, much time, trouble, and annoyance are saved.

It would be impossible to give in detail all the medical matters of interest which are referred to in this volume; but suffice it to say that we have presented to us an account of all the medical societies, medical institutions, hospitals, dispensaries, throughout the city, while all the officers of the county societies are given, and all the members of the same. The list of nurses, artificers in medical appliances, and instruments, and of regular educated dentists will serve as a guide to those who may be in need of recommendations.

The obituary notices are full, and are written with that ease, elegance, and taste which, even independent of the interest that may be taken in the subjects of the sketches, will command for them a wide reading.

We have not deemed it out of place in these columns thus to allude to the work before us. Although the editor is known to our readers as a valued contributor to our columns, it is no reason in itself why any outside emanations from his pen should not receive the same notice as would those of a stranger, and entitle us to the privilege of praising or condemning his efforts in absolute accordance with an impartial judgment. This part of our task we have endeavored faithfully and conscientiously to fulfil, and lay down the volume with our unqualified approbation.

THE MINERAL WATERS OF THE UNITED STATES AND CANADA; WITH A MAP AND PLATES, AND GENERAL DIRECTIONS FOR REACHING MINERAL SPRINGS. By J. J. MOORMAN, M.D., Resident Physician at the White Sulphur, Lecturer on Anatomy and Physiology, Roanoke College, Va., etc., etc. Baltimore: KELLY and PIET, 1867. 12mo., pp. 507.

As the work is written for the public, it cannot be expected to serve the purposes of a scientific treatise. It is true there is not a little, in a general sense, that may be of value to the physician in reference to the localities and properties of the different Spring waters, but further than this the book is seemingly written more to amuse than instruct, and will doubtless serve its purpose in filling up a gap in what the author chooses to call "Spring literature." The work is decently printed, and has scattered through its pages several indifferent lithographic representations of the different Springs and their surroundings.

ESSENTIALS OF THE PRINCIPLES AND PRACTICE OF MEDICINE: A HANDY BOOK FOR STUDENTS AND PRACTITIONERS. By HENRY HARTSHORNE, M.D., Prof. of Hygiene in the University of Pennsylvania, Auxiliary Faculty of Medicine, etc., etc. Philadelphia: HENRY C. LEA, 1867. 12mo., pp. 417.

THE work before us is stated to be "an unambitious effort to make useful the experience of twenty years of private and hospital medical practice, with its attendant study and reflection;" and so well has the author accomplished his object that we cannot refrain, despite our prejudice against handy books in general, from pronouncing it a remarkable success. The arrangement of the subjects is most judicious and unexceptionable, and the manner in which he treats of the "essentials" of medicine is in the highest degree satisfactory to the reader.

The work is divided into two parts, the first referring to the Principles of Medicine, under which heading General Pathology, Semeiology, General Therapeutics, and Nosology are discussed; and the second, under the caption of Special Pathology and Practice, gives us an insight into the functional, systemic, and organic affections, with their diagnoses, prognoses, treatment, etc. Then follows a list of formulæ which the experience of the author has approved of in the different ailments, and lastly, a general index.

The introduction to the work gives us, in a remarkably concise and comprehensive manner, an exhaustive history of the different systems of medicine that have prevailed, and altogether, stamps Dr. Hartshorne as a scholar of no ordinary pretensions. The main part of the work is of a decidedly practical character, and the effort to condense every essential point in the smallest possible space gives a value to the book that is decidedly peculiar. We must not be considered as recommending the work for more than it really is, a simple record of the experience of a thinking and practical man, one who has given ample evidence that he understands what the title of his little book implies. We have perused it diligently, and we hope impartially, and lay it down with naught but commendation.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, JUNE 27, 1867.

DR. H. B. SANDS, PRESIDENT, in the Chair.

REPORT OF COMMITTEE ON DR. CUTTER'S SPECIMEN.

DR. ROGERS, as one of the committee appointed at the previous meeting to report upon Dr. Cutter's specimen of diseased spleen, offered the following:

The undersigned member of the committee of two, appointed by the President of the New York Pathological Society, to examine and report upon the true character of certain specimens presented to the Society at its meeting of the 12th of June, inst. by Dr. Cutter, at the request of the other member, Dr. Cutter, has examined the specimens, and reports that, after repeated and careful examinations of the specimens furnished him by Dr. Cutter, from both the stomach and uterus, he failed to discover any evidences of any kind of cancerous disease.

Even the physical character of the specimens furnished did not present anything abnormal. He wishes to be understood as making this report upon the material furnished him only, without even supposing that they were well selected and representative specimens of the alleged diseased structure. In relation to the cyst found attached to, or developed from the spleen, he found it to be a pure specimen of cholesteatoma.

The members of the Society who saw the specimen, will appreciate the following as a graphic description of its appearance to the naked eye; and your reporter testifies to its faithfulness, in respect to the microscopic appearances. It occurs in Mr. Paget's lecture on what he terms "Compound or Proliferous Cysts," at p. 393, and reads as follows:

"In the opposite extreme to these cysts, in which the cuticular product is most perfect, we find an innumer-

able variety of contents, of buff- and ochre-yellow, and brownish materials, that seem to consist mainly of degenerate cuticle mingled with sebaceous secretions. The microscope finds in them a confused mass of withered scales, of granular fatty matter, clustered and floating free, of cholesterine crystals, and of earthy matter in free molecules, or inclosed within the cells or scales, and all these may be floating in a turbid liquid, or retained in some soft tenacious mass, or clustered in hard, nodular, and pointed masses, projecting like stalactites from the old cyst-walls."

Nor in this character does it appear to be a unique specimen. Dr. Gross, in speaking of cysts affecting the spleen, remarks that they may contain a clear limpid fluid like spring water, in other cases they may be occupied by a sort of meliceric, atheromatous (which means composed more or less largely of cholesterine crystals), or steatomatous substances.

In conclusion your reporter begs leave to state, that while he declares that the portions of this cyst and contents submitted to him, were purely cholesteatoma, he does not deny that the cyst may have possessed other constituents, of a cancerous character. Mr. Curling cites several examples of cholesteatoma associated with malignant disease in the same tumor or person, and one case of this form of disease in a testis, with which enchondroma and encephaloma were combined.

URINARY CALCULI, ETC.

Dr. Post exhibited a urinary calculus which resembled very much the charms said to have been worn by the Roman ladies, being representations of the penis with the scrotum attached. It was removed by the lateral operation of lithotomy from a boy 13 years of age, who had complained of symptoms of stone in the bladder ever since he could recollect. The stone was readily detected on sounding, the sound emitted by the steel instrument indicating it to be of a light and porous nature. On introducing the forceps, the stone was seized by its small extremity, causing it to be broken, the larger portion being afterwards removed. The operation was performed at 2 o'clock on the Wednesday previous, and at 9 o'clock in the evening, having a desire to urinate, the patient passed a large quantity of urine tinged with blood. Since then he has had three discharges a day by the natural passage. The first evening after the operation the pulse was 130, attended with some febrile heat; it however soon subsided, and on the Monday following his pulse was 80, and he was able to get about the room quite comfortably. The calculus weighed 107 grains, was 1¼ inches in length, ¾ of an inch in breadth at the larger extremity, and $\frac{1}{16}$ at the smaller extremity. A small portion was analyzed by Dr. Wm. B. Lewis, and was found to be composed chiefly of phosphate of lime, with a small trace of the triple phosphate, and carbonate of lime.

He also exhibited a calculus, salivary in character, removed from the Wharton's duct of a patient 60 years of age. This body had existed under the tongue for 7 or 8 years, but had given no trouble until a month ago, when great difficulty of mastication was the result of its presence. When it was extracted it was found to have a remarkable prominence at one end, and was marked by tapering at the other. It weighed 28 grains, was ¾ of an inch in length, and ½ an inch in breadth at its broadest portion.

Dr. Bauer exhibited a specimen of aneurism of the arch of the aorta, for the purpose of affording the junior members present an opportunity of viewing a typical case. It was situated on the anterior portion of the arch, and by its pressure gradually absorbed the cartilages and ribs, as well as a portion of the sternum in its neighborhood.

EXTIRPATION OF INTRA-UTERINE FIBROUS TUMOR.

He next presented an intra-uterine fibrous tumor which he had removed by operation that morning. The diagnosis of the case had been made 5 years ago. The patient was 49 years of age and had four children, the youngest being 12 years old. Four years ago Dr. Bauer was called to attend her for hæmorrhage of the uterus, and on examining her carefully he discovered an intra-uterine tumor, probably fibrous. Dilatation was commenced, as it was necessary to do so in order to treat the symptom of bleeding. The treatment of dilatation was carried on to that extent that at the end of a year afterwards he could introduce his three fingers, and allow the tumor to come out. Soon afterwards the patient, formerly a resident of Brooklyn, had removed to this city. She went on occasionally having her attacks until she began to suffer from an extremely fœtid discharge, and having sent to a neighboring physician, and he having pronounced the case one of cancer, she became very much alarmed, and sent for her old attendant. Dr. Bauer, on examination, found the tumor protruding though the os, and also discovered that its fœtid odor was due to ulceration and sloughing of its lower portion. The only resource was the operation of enucleation, which was done without the slightest difficulty. It seemed to be attached directly to the mucous membrane, no distinct pedicle being discoverable. On microscopical examination it was found to be purely fibroid in character.

Dr. Weir, after exhibiting a specimen for a candidate, presented several specimens of the distoma hepatica, which he had accidentally met with in the rectum of a patient upon whom he was operating for extravasation of urine. The patient stated to him that he had been in the habit of passing them for several years. His life was terminated by diarrhœa. No post-mortem examination was made.

PENDULOUS ADIPOSE TUMOR.

Dr. Sayre exhibited an adipose tumor removed by operation from the outer portion of the right clavicle of a woman, 35 years of age, who, strange to say, had carried it for 8 years without an operation. She was brought to the hospital on account of hæmorrhage occasioned by ulceration into a large vein upon its surface. It weighed 1 pound and 9 ounces, and there were 9 large veins found upon its surface, and one large artery through its substance.

He also presented a tumor of the same character which he had some time before removed from the upper and inner portion of the right thigh, which had such a long pedicle that it had been diagnosticated by some who saw it as pediculated fibrous tumor.

Dr. Markoe remarked that the last tumor had pediculated on account of its weight, while there evidently did not exist such an attachment from the commencement as would have been the case in the pediculated tumor.

REPORT OF COMMITTEE ON DR. FINNELL'S CASE OF INTRA-UTERINE TUMORS CAUSING DIFFICULT LABOR.

Dr. Rogers then offered the following report of the committee to examine into the condition of the intra-abdominal tumors in the fœtus presented at the previous meeting by Dr. Finnell.

The undersigned committee, appointed by the President of the New York Pathological Society at the meeting of 12th June, 1867, to examine and to report upon the true character of the two tumors presented by Dr. Finnell at that meeting, respectfully report, that

the required examination has been instituted, and the following result arrived at:

The committee would first, however, beg leave to premise, that the history of the specimens as given by Dr. Finnell at the time of presenting them, having included the statement that all of the viscera of the ventral cavity were present, and in a healthy condition, and that it was a male fœtus whose testes were *not* sought for, nor examined, and consequently not known to be present, had, as the Society will recollect, directed the attention of some of its members to the fœtal testes, as the starting-point of the enormous tumors—enormous when compared to the healthy fœtal gland. The absence of any report relating to the testes of the fœtus, was indeed the chief cause of the necessity for the formation of the committee. For with a perfectly healthy condition of the abdominal viscera of a male fœtus, and the existence of two exactly similar tumors, perfect duplicates of each other, occupying the two lateral regions of the cavity, and each provided with a similar duct or vessel, this mass could scarcely be regarded as anything else than diseased testicle, had no testicles been found elsewhere.

In the absence of this important evidence, the committee were forced to resort to histological proofs in the formation of a conclusion as to the character of the growths. The form of the growth is that well known in pathology as *fibro-cystic*. The cysts are of all possible sizes, from an almost imperceptible vesicle to the quarter of an inch in diameter, and, as we believe, are lined by a delicate membrane, possessed of tesselated epithelium. At least this is the fact with the cysts large enough for examination.

On carefully dissecting the tumors, each one is found to have a duct or vessel, of sufficient size to admit a common probe. The microscope shows that this duct or vessel is lined by an epithelium of the columnar variety. Tracing it deeper into the substance of the tumor, this duct is found to be an outlet from a kind of sinus extending in the direction of the long axis of the tumors for about half its length. This sinus has several communicating, or tributary ducts leading into it from various parts of the tumor, and is precisely similarly located and provided in the two, and possesses the same variety of epithelium as the duct. Besides this duct, each tumor has a vessel of very small size, possessing all the characteristics of an artery, leading into its substance, another having the appearance of a small vein, and lined with scaly epithelium, and between these two vessels is also found a nerve branch accompanying the vessels in their distributions. Under the microscope, the nuclei of the neuralemma of this nerve twig are very distinctly visible, and render its nervous character unequivocal. These three are united in one pedicle or cord, and are located at a slight distance from the large duct. Now as this is precisely the histological description of the spermatic cord and the epididymal portion of the spermatic duct, and of nothing else, further proof in support of the belief that these tumors are examples of fibro-cystic disease of the fœtal testes does not appear necessary to the committee. Desiring, however, to leave no point uninvestigated, the following extract from Mr. Paget's lecture on fibro-cystic tumors, will explain why the committee extended its microscopic examinations. He says: "We find examples of fibrous tumors thickly beset with numerous well-defined and lined cysts. This appears to be the nature of the 'hydatid testis' described by Sir Astley Cooper. The specimens that I have seen of it make me think that it is essentially a fibrous tumor in the *testicle*, with cyst formation in the tumor. For, upon or around the tumor, the seminal tubes or their remains may be traced outspread in a thin layer, and without difficulty separable, and the substance of the tumor is a distinct mass of common fibrous tissue, with a variable number of imbedded cysts, filled with pellucid serous or viscid contents." The committee hardly expected to find any such layer of seminal tubes over this tumor—the size of, and very nearly the shape of half of the fully developed fœtal brain—for the fœtal testis, which is about as large as a medium-sized pea, spread out to that degree, could with difficulty be detected. But in the hope that it might have been differently disposed of, we commenced the microscopic examinations of various portions of the substance of the mass, and very soon found undoubted fragments, of both the straight and the convoluted seminal tubes, lined with their characteristic cells. The whole tumor contains vast numbers of spindle-shaped nucleated fibro-plastic cells, and exudation corpuscles, and in some regions much mingled with these seminal cells. These fragments of the testis seem scattered over a great part of the tumor, for we have detected them in portions taken from widely distant parts. The locality of these fragmentary portions of the testis is generally marked by a slightly yellow tinge of the substance of the tumor, and a less cystic character of the point thus tinged. These fragments are mostly located near the sources of the vessels or ducts we have described as tributary to the longitudinal sinus of the tumor, and can with great certainty be pointed out. All doubt, therefore, in the minds of the committee, as to the testicular origin of the tumors, has been removed. But as to the precise pathology of the tumors, the committee see difficulty in demonstrating that the disease was originally of the fibro-areola tissues of the testis or of the cell-tubes, that is, whether it was a pure fibro-cystic disease, or whether it was in part a glandular tumor of the testis. If it be in part what is known as a "glandular proliferous cyst," distinguished by the presence throughout its substance of structure exactly similar to that of the gland upon which it is developed, it can be so only to a small degree, for large portions of the tumor are devoid of such structure. The committee thereupon incline to the opinion that it is a pure fibro-cystic disease in the testis of the fœtus.

The committee entertain the theory, that the part of the duct present in the specimen, corresponds to the epididymis, and represents that part of the seminal duct in a straightened and dilated condition.

This view receives the confirmation of the best authorities upon the minute anatomy of the testis and its ducts; the epididymis being, according to them, the only portion of the seminal passage lined by columnar epithelium.

The longitudinal sinus represents the rete-testis in a dilated state, forming an irregular but common canal; and the tributary ducts opening into it are the diseased and dilated vasa recta of the original testis.

In conclusion, the committee would add, that it has been unable to obtain any information of the record of a similar case of fœtal disease, and that thereupon, so far as it knows to the contrary, this is an unique case in pathological history.

STEPHEN ROGERS.
F. C. FINNELL.
E. KRACKOWIZER.

EXECUTIVE SESSION.

Minutes of previous meeting read and approved.

Dr. G. H. Wynkoop was elected a member.

On motion, the Society adjourned until the second Wednesday in September.

Adjourned.

Correspondence.

"THE UTERINE ELEMENT IN PRACTICE" AGAIN.

To the Editor of the Medical Record.

Sir—In some of the operations now undertaken with the uterus, is there not some danger of doing harm, even endangering life? Can it be slit up, have its cervix dilated with sponge-tents, injections thrown into its cavity, etc., without any hazard, if discrimination and caution be not exercised? As bearing on this point, I quote a statement in the *American Medical Journal* in a notice of the Transactions of the Obstetrical Society of London: "Dr. R. Greenhalgh presented a paper on mechanical dysmenorrhœa, in which he states that he had operated upon nearly three hundred cases of this affection, with but few and slight casualties. In one there was rather profuse hæmorrhage, for which plugging was had recourse to. In about five others pelvic cellulitis ensued, a casualty which is by no means unfrequent after the use of sponge-tents. In one peritonitis was set up, and terminated fatally." Are such incidental casualties, resulting in one case in death, not to be taken into the account? Should they not admonish to the practice of some caution? Should they not hinder young practitioners from plunging headlong into uterine practice? There is no part of the physician's business that requires more accurate discrimination, and the specialty of the treatment of female diseases ought not, therefore, to be entered upon at the beginning, but it should be a gradual outgrowth from a general practice, gathering up its stores of diagnosis in the course of long years. This being so, it is not wonderful that we have occasional revelations of great blunders in the diagnosis and practice of newly-fledged practitioners in female diseases. I have known one, who flourished largely with the speculum, to mistake a head for a breech presentation, when the head could be distinctly felt passing down through the well-opened os uteri, showing that his touch was not well educated—however it might be with his sight—and I have known another to diagnose grave disease of the uterus and prescribe accordingly, when the occurrence of abortion, before the remedies were applied, revealed the true nature of the case. Other mistakes could be cited, but these will suffice. I remark, in passing, that the errors committed from lack of experience in those who undertake early in their practice to foist up a reputation for the treatment of female diseases are undoubtedly frequent, for the few that accidentally come to light must be a small portion of those which actually occur.

I have spoken in a previous article of the commonness of the error of supposing ulceration of the os uteri to exist when it does not. I have no doubt that quacks and demi-quacks (of whom we have many in our ranks) often call the slightest patch of redness an ulcer, or even pretend that one exists where there is not the shadow of disease to be seen on the organ. In this latter case the patient may appear to be cured by the local application, and may give the doctor great praise for having found out just what the matter is, as it is expressed, and for knowing just what to do. And yet it is the general remedies that have, of course, effected the cure, while he may have merely pretended to apply the nitrate of silver, or, if he has really applied it, his light touches have inflicted no damage that is not readily recovered from by the membrane. Indeed, I have no doubt that even when there is considerable of that lesion which I have spoken of as being by far more commonly found on the os uteri than any other, general treatment alone may often succeed without any local application—that it often did before the speculum was introduced into practice, though it is very certain that judicious local treatment may be of essential service in such cases. To attribute all or most of the symptoms to this lesion where it exists, as is often done, is a great error. In most cases it is a small part of the difficulty, and in many it is one of those local ailments that have their origin in a general condition. I will quote here what Guerin says of the symptoms attributed to the so-called ulceration:

"As the human mind has a great tendency to assign effects to causes which it can readily appreciate, the pains which women so frequently experience in their loins and abdomen have generally been attributed to ulceration of the uterine neck. This ulceration answers to all—pains of the stomach, of the kidneys, dyspepsia, hysteria, nervous affections of all sorts—everything is explained by excoriation of the uterine neck. After having examined many thousands of women, I think myself right in affirming—

"*First.* That these ulcerations cannot cause the pains which have been attributed to them.

"*Second.* That these pains are caused, in a very large majority of cases, by phlegmonous inflammation of the large ligament, by an ovaritis, a pelvic peritonitis, or by a hæmatocele, or finally by an intestinal lesion to which the physician gives no farther thought when he has discovered an ulceration, however slight, of the neck."

I remark, in passing, that it is doubtful whether the symptoms mentioned are as frequently to be attributed to these local diseases as Guerin states—very often they are either functional or nervous results, dependent, sometimes, undoubtedly, upon a morbid general condition, which must be relieved by general remedies.

Guerin thinks that the usefulness of the speculum has been vastly overrated, while that of the touch has been as much undervalued, of late years, in the investigation of the diseases of the uterus. If the question were between not using the speculum at all and using it as excessively as many do, I am free to say that the former is preferable—in other words, I believe that those who rely upon the symptoms, together with what they can discover by the touch, when that is necessary, really make out, in the great majority of cases, a more correct diagnosis than those who make so very much of the diseases of the uterus, and especially of its os, and use the speculum with great freedom. While the latter think, generally, altogether too much of the local disease, and perhaps sometimes find such disease when it has no real existence; the former, though indeed failing, sometimes, to appreciate truly what is local, will, with few exceptions, meet properly the necessities of the case. It is these exceptional cases that the speculum is needed to take care of fully. Practically the use of the speculum is required in some cases besides these, for disease of the os may be occasionally suspected where it does not really exist; but allowing all proper latitude for its use as a means of investigation, it need not be frequently employed.

There is one item in the practice of some who have so frequently found ulceration of the os uteri, that deserves a slight notice. It has been common to enjoin rest upon the bed for some time after applying the nitrate of silver. I have never found this necessary in any cases where I have applied it, that is, on account of its application, though it may have been sometimes necessary for other reasons. But the expedient certainly gives importance to the local treatment in the eyes of the patient, and is quite a useful part of the programme with the cunning and quackish physician.

Far be it from me to undervalue recent researches in uterine pathology, and the multiform contrivances for investigating and treating diseases of the uterus. At the same time I must say that while with many most flagrant abuses exist in connection with their treatment —often actually quackish—even with the best there is apt to be too much made of local disease, and not enough of that which is general. It is precisely as it has been with various local diseases from time to time —for example, to take a recent instance, what has been called the clergyman's sore-throat, an error which has had its day and is now fast passing away.

The practice of the abuses which I have noticed in the treatment of female diseases is doing much harm in various ways. It hinders from proper investigation, some being so disgusted with Balbirnie, and his succession of apostles of the speculum, that they will not use the instrument at all. It encumbers our journals and other records of the profession with false facts. Not only the statements of those who stoop to quackery, but those of men who have exclusive and one-sided views, mislead the profession and embarrass its investigations. And beyond all this, it brings discredit on the profession, and gives currency to that miserable delusion, the necessity of having female practitioners to be devoted especially to the care of female diseases. The honorable and high-minded physician never need to offend a true delicacy in using all necessary means for the investigation and treatment of disease, but unnecessary measures may so offend, and their influence is wider than in the particular cases in which they are used, and tends to mar the standing of the whole profession, and put it into a false position. *

ANOTHER NEW POST-MORTEM NEEDLE.

To the Editor of the Medical Record.

Sir—In the "Record," of July 15th, a post-mortem needle is described and illustrated, which, while supplying a more available means than the ordinary needle for the purpose, is yet surpassed by an invention that I beg leave to describe, and which I have found invaluable where many autopsies were to be made, and time precious.

It is the invention of an Irishman, the most wonderfully ingenious man I think I have ever met, but whose devotion to rum blasted every project, and brought him from the outset below the chance of fame. Among his thousand inventions, he had devised a sewing-machine for his wife, which was used in his home long before the possibility of such a machine had been demonstrated by a more energetic inventor, to the public. What his real name was, I cannot say; but at the time of his invention of the post-mortem needle, he had fallen to be plain dead-house man at Flatbush Hospital; and, to show how revoltingly debased the appetite for liquor may become, he would drink the alcohol from our choicest pathological specimens, and fill up the jars with water—but to the needle:

The instrument has a straight firm handle with a needle fastened into it like an awl, curved near the end and perforated at the extremity like the one referred to in the "Record" of the 15th inst. A common spool, holding the thread, is so placed upon the needle in its long axis near the handle as to easily revolve and cause the thread to unwind when necessary. The free extremity of the thread is passed through the eye of the needle, forming a loop.

The operation of the instrument is simple—it is passed through both edges of the cut, the loop of thread is then caught between the thumb and finger, drawn onward, the needle withdrawn as with an aneurism needle; the handle, needle, and spool are then passed through the loop and drawn tightly. The result is a lock-stitch.

The instrument has never, so far as I am aware, been presented to the profession; but it is so simple, so efficient, and may so readily be made, that it will commend itself. A more delicate needle would be a valuable addition to a pocket-case for ordinary wounds

Yours truly,

E. Holden, M.D.

105 Orange Street, Newark, N. J.

Obituary.

ALFRED ARMAND LOUIS MARIE DE VELPEAU,

of paris,

Whose death was announced by an Atlantic cable telegram as having occurred Aug. 23, ult., was born May 18, 1795, at Brêche in the department of Inde et Noir. The son of a poor, easy-going, kind-hearted blacksmith, who had destined him for the same trade, his advantages for even a rudimentary education were quite limited—so much so, indeed, that he learned to read from three books, which constituted his father's library. These, which at the age of ten years he could recite *verbatim*, were a treatise of *Hippocrates*, the *Rustic Mason*, and the *Poor People's Physician*. Having thus thoroughly mastered their contents, he began to practice writing, and soon became proficient enough in arithmetic to keep his father's small scores.

About this time a curate who had been sent to Brêche, opened a school for gratuitous instruction, at which the most attentive and eager student was our eminent surgeon of the future. The death of this preceptor, at the end of only a four months' residence, again interrupted his plans. In his sixteenth year, however, he was befriended by a physician from a distant village, who procured for him the privilege of prosecuting his studies in the family of a wealthy gentleman. This mine, it is needless to say, was well worked.

Having taken up his residence at Tours, a populous town some eight leagues distant from his birthplace, he became, after only fifteen months of study, the envied possessor of the diploma of "Officier de Sante," and soon after "Interne" of the Hospital. These honors he attained while practising the most rigid economy, living, says one authority, "on a scanty supply of coarse bread and cheese, sent to him once a week by his thoughtful mother." He subsequently became first-assistant to Monsieur Bretonneau, surgeon of the hospital at Tours, attending to his private patients and occasionally collecting a well-earned odd fee on his own account, —all of which brought him into notice, and indirectly added to the income of two hundred francs allowed by the hospital to servitors of his grade.

An affair of the heart, however, in which a fickle maid played an important part, provoked him to abandon Tours for Paris, supplied only with a loan of ten Napoleons and a letter from his friend, Monsieur Bretonneau, to the excellent Dr. Jules Cloquet. Here, studying, following the hospitals, and still fighting hand-to-hand with his old enemy, poverty, he was advised by Dr. Cloquet, whom he soon numbered among his friends, to take his chance at the public Concours, an institution which looked for only one qualification in a candidate, ability to stand the test of its examination. In this way he won his position in the Hospital St. Louis, where he remained three years. He is next found the

private assistant of Monsieur Bongon, surgeon to the Duke de Berry. The Concours now awarded him still another honor, that of "Aide d'Anatomie" to the faculty. In May, 1823, he graduated, and in the following year was appointed "Professor Agrégé." A surgeon of the Bureau Central in 1828, he still found means for constant improvement, and although an acknowledged chief, the impartial Concours refused him the chair of "External Pathology," which he so obstinately contested. In 1830, the Concours returned three names for the Obstetrical Chair as equal in merit—Moreau, Dubois, and Velpeau, the first of whom was chosen. In his last contest, which was in 1835, he won the chair of Clinical Surgery.

Velpeau was a member of most of the scientific bodies with which Paris abounds, and in 1859 attained the dignity of "Commandant in the Legion of Honor." A judicious operator, a voluminous writer, a lucid lecturer, and an indefatigable student, he well deserved the title given him by one of his admirers, of "King of Surgeons." He died of nephritis.

MICHAEL FARADAY, D.C.L., F.R.S.,

OF LONDON.

Prof. Faraday, the eminent English chemist and natural philosopher, who died in London, England, August 27, 1867, was born in Surrey, England, September 22, 1791. His father being a working smith, the deceased was unable to obtain other than the most ordinary education at a common day-school. When a lad of thirteen years, he was apprenticed to a London bookbinder, and having, through his position, the means of obtaining several scientific works, he studied them carefully, and by the assistance of a treatise on electricity, was enabled to construct his first electrical machine with a glass phial. Subsequently, through the kindness of a member of the Royal Institution, Mr. Faraday obtained permission to attend the last four lectures of Sir Humphrey Davy, in 1812. He afterwards sent to the kind-hearted philosopher a copy of the notes he had taken, and requested his assistance to enable him to "escape from trade, and to enter into the service of science." Sir Humphrey, after ascertaining the ability of the applicant, promptly complied with his request, and made him his chemical assistant at the Royal Institution. The deceased subsequently travelled throughout Europe as the assistant and amanuensis of his patron, and on his return to England resumed his position at the Royal Institution. The progress of Mr. Faraday was now rapid and successful. In 1820 he discovered the chlorides of carbon; in 1821 the mutual rotation of a magnetic pole and an electric current, and in 1823 his exertions led on to the condensation of the gases. In 1833 he became the Professor of the new chair of chemistry at the Royal Institution, a position he ever after held. The honors which his own and foreign governments and institutions bestowed upon him for his services to science were numerous. He was a Commander of the Legion of Honor, Knight of the Prussian Order of Merit, Fellow of the Royal Society, Doctor of Civil Laws, one of the eight foreign Associates of the Imperial Academy of Sciences at Paris, besides being a member of many learned and scientific bodies in Europe and America.

Dr. JAMES JACKSON,

OF BOSTON, MASS.

The Boston papers announce the death of this physician as having occurred August 27th, at the age of ninety years. Dr. Jackson was a native of Newburyport, Mass., where he was born on October 3, 1777. In 1796 he graduated at Harvard College, and in 1802 was admitted to the Massachusetts Medical Society. He soon won a high position in his profession, and in 1812 became Professor of the Theory and Practice of Medicine in the Harvard Medical School, which position he held for twenty-four years. He was also one of the founders and physicians of the Massachusetts General Hospital, and was elected President of the Medical Society several times. About eighteen months ago his faculties suddenly failed, and thenceforward his physical powers gradually declined. His death appeared to have been caused more from old age than from any local disease.

J. MASON WARREN, M.D.,

OF BOSTON, MASS.

Dr. J. Mason Warren died at his residence in Boston, of cancer of the bowels, Aug. 20. Thus, another bright light in American surgery has been extinguished. Dr. Warren's family is well known in the medical history of New England. The names of his father, Dr. John Collins Warren, and of his grandfather, Dr. John Warren, will always be associated with that of Mott, as pioneers in the surgical field of America. With the rich inheritance of his name, and, in our opinion, with more ability than his father or grandfather, though with less sternness of character, and less desire to attain notoriety, Dr. J. Mason Warren acquired a large surgical practice, and was undoubtedly looked upon as the greatest surgical authority by the public of New England and the British Provinces.

It was the writer's good fortune to have served under Warren at the Massachusetts General Hospital, and in later years to have met him often as a friend. Pleasant is the memory of those days passed in intercourse with Townsend, Heyward, Bigelow, Sam. Parkman, and Warren, of whom only Townsend and Bigelow still remain. Where else could be found a surgical corps of such genial, honorable men, and such able enthusiasts in their profession? Each had his peculiar traits, each his special excellencies.

To us internes, or "pupils," as the Trustees of the Mass. Genl. Hospital have unwisely dubbed the house staff of that institution, Warren's *forte* was the conscientious care, and the assiduous attention which he devoted to every patient who came under his charge. Others could operate with more apparent boldness, and with greater coolness than he. Before a serious operation he would vent his nervous excitement by walking up and down the amphitheatre aside. His hand might tremble as he took the knife; but once the operation commenced, all signs of agitation ceased; then no fingers were steadier than his, no greater skill and delicacy of manipulation could be shown. But it was *par excellence* after the operation that Warren won our admiration by his rare combination of the physician with the surgeon. Early and late, if circumstances required, and at the sacrifice of private practice, he would visit the hospital and watch over his patient. The minutest detail received attention. Every contingency was provided for. The richest man on Beacon street could have received no greater care. It is hardly necessary to add, that he thus endeared himself to every patient, and commanded the esteem of his assistants. His success as an operator was also dependent in a great measure upon this fact.

In all our dealings with him as internes, Mason Warren was always the same—kind, considerate, gentlemanly, at the same time that he was exacting in the rigid performance of our duties; not from the policy which might lead some "visiting surgeons" to mend

their ways, but from the kindly nature born in him. His intimate friend and fellow-student, Dr. Oliver Wendell Holmes, in a touching tribute to his memory, such as Holmes only could write, says, that in all their intercourse he never knew of an unkind or harsh word between Warren and his associates.

With less modesty and less of a retiring disposition, and with more desire for fame, Warren might have secured a wider reputation, to which he was fully entitled. His contributions to surgery were chiefly reports of cases, published in the current medical literature of the day. He, however, lived to complete a most elegant work, which will remain a monument to his memory and an honor to American surgery, entitled "Surgical Observations, with Cases," and bearing the date of 1867.

We have lost in Warren a skilful surgeon, a true friend, a noble and upright man. B.

DR. JOHN HART,

OF NEW YORK.

At a regular meeting of the "East River Medical Association of the City of New York," held September 3, 1867, the following preamble and resolution were unanimously adopted:

Whereas, It has pleased the Almighty Ruler of the Universe to remove from our midst Doctor John Hart, a valued friend and associate; and

Whereas, In the loss of one so intimately connected with the East River Medical Association, and so prominently and honorably identified with its existence and aims, it becomes us as members of the Association, to give an earnest expression of our great sorrow in this untoward bereavement; therefore, be it

Resolved, That as a conscientious practitioner of medicine—as a genial friend—as a zealous member of this Association (of which he was one of the originators)—as an exemplary and faithful presiding officer—his character has commanded our respect, and his memory will always be cherished.

Resolved, That a copy of the foregoing be published in the medical journals of this city.

MICRO-CHEMISTRY OF POISONS, INCLUDING THEIR PHYSIOLOGY, PATHOLOGICAL AND LEGAL RELATIONS; adapted to the use of the Medical Jurist, Physician, and general Chemist. By THEO. G. WORMLEY, M.D., Prof. of Chemistry and Toxicology in Starling Medical College, and of Natural Sciences in the Capital University of Columbus, Ohio. With seventy-eight illustrations on steel. New York: Baillière Bros. 1867. 8vo., pp. 668.

CHEMISTRY. By WILLIAM THOMAS BRANDE, D.C.L., F.R.S., L. & E., of Her Majesty's Mint, and ALFRED SWAINE TAYLOR, M.D., F.R.S., Fellow of the Royal College Physicians of London. 2d American edition, thoroughly revised. Philadelphia: H. C. Lea. 1867. 8vo., pp. 764.

ELEMENTS OF MEDICAL CHEMISTRY. By B. HOWARD RAND, Prof. of Chemistry in Jefferson Medical College. Philadelphia: T. Elwood, Zell & Co. 1867. 12mo., pp. 399.

THE PHYSIOLOGY OF MAN, DESIGNED TO REPRESENT THE EXISTING STATE OF PHYSIOLOGICAL SCIENCE AS APPLIED TO THE FUNCTIONS OF THE HUMAN BODY. By AUSTIN FLINT, Jr., M.D., Prof. of Physiology in Bellevue Hospital Medical College, N. Y. Alimentation, Digestion, Absorption, Lymph, and Chyle. New York: D. Appleton & Co. 1867. 8vo., pp. 556.

PHYSICIAN'S VISITING LIST FOR 1868. Philadelphia: Lindsay & Blakiston.

INJURIES OF THE EYE, ORBIT AND EYELIDS, THEIR IMMEDIATE AND REMOTE EFFECTS. By GEORGE LAWSON, F.R.C.S., Eng., Assistant Surgeon to the Royal London Ophthalmic Hospital, Moorfields, etc. Philadelphia: H. C. Lea. 1867. 12mo, pp. 408,

Medical Items and News.

PERSONAL.

Professor Agassiz is superintending the illustrations for his "Journey to Brazil," the work being all written and in the printer's hands.

Surgeon P. G. S. Ten Broeck has been ordered to Fort Preble, Maine, to relieve Assistant Surgeon F. Le B. Monroe.

PROF. HYRTL, of Vienna, received a gold medal at the last Paris Exhibition for his anatomical preparations, and Prof. Trichmann, of Cracow, the bronze for the same. Dr. Politzer, of Vienna, received an "honorable mention."

AUSTRALIAN LEECHES are just now threatening to compete with those of the Swedish and Hungarian variety. They are principally collected in and near the Murray river, and it is said that sometimes 250,000 are shipped by a single steamer for the English market.

THE CHEMICAL NEWS AND JOURNAL OF PHYSICAL SCIENCE.—Messrs. Townsend & Adams, of this city, have undertaken to republish in this country this well-known and highly esteemed British periodical. It is to be issued in monthly parts instead of being, as is the original, a weekly issue. It is, typographically speaking, well executed. The enterprise of the publishers deserves substantial support.

GILDING BY AMALGAMATION.—M. Dufresne, of Paris, has introduced a new process for gilding. He first covers the article to be gilded by decomposing a basic salt of mercury, by means of a galvanic battery, then precipitates gold by the same means upon it, and lastly covers the article with another deposit of mercury. The article is then heated in a furnace until the mercury passes off as a vapor, when the coating of gold is found adhering to every part of the surface. If the volatilization of the mercury is carried on in a close furnace, there will be no danger to the workmen.

THE NEW YORK CITY INEBRIATE ASYLUM.—The building about to be erected by the Commissioners of Public Charities and Correction upon Ward's Island, N. Y., for the reclamation of drunkards, will be of brick in the mediæval style of architecture, with Mansard roof and ventilating turrets. In its construction the pavilion plan will be adopted—the pavilions to be each 39 feet wide by 121 feet long, and the corridors 17 feet wide by 58 feet long.

The expenditures, with a view to ensure the modern improvements in the matter of ventilation, heating, wash-rooms, water-closets, baths, etc., will be on a liberal scale.

A NEW METHOD OF PRESERVING THE DEAD.—There is now on exhibition at the New York Morgue the body of a drowned man supposed to have been in the water for three days prior to its recovery, and which is being

subjected to an experimental preservation. It is inclosed in a metallic case, made perfectly air-tight, and, as yet, although forty days have elapsed since the commencement of the experiment, shows no signs of decomposition. This result is obtained by forcing the air from the case and supplying its place with a certain gas, which the discoverer, we regret to state, is inclined to keep secret. He even expresses the belief that the body in course of time will become as hard as stone.

Professor Follin, the distinguished Surgeon and Oculist, who died in Paris lately, was forty-three years of age.

A new Hospital (pavilion) is to be built in Berlin.

Dr. Meadows, of London, has been elected an honorary member of the Obstetrical Society of Berlin.

Dr. Racle, Assistant Professor in the Paris University, is dead. He was so poor, although a famous author, that the cost of his burial was paid by his colleagues.

The Cattle Plague has appeared in the province of Old Castile, in Spain.

The Percentage of Deaths in the Hospitals at Hong-Kong is quoted at thirty-three and a half. This is said to arise from the fact that Chinamen are only brought to the hospital by their friends when in a dying condition. Some place those who are dying out of doors, in order to save the cost of burial, when they are picked up and carried to the hospital by the police.

The Exhaustion of the Native Population of the Sandwich Islands, which has been going on for a great number of years, seems to be accelerated of late. During the last six years there has been a decrease of over 9,000. The death rate among the natives is now about 1,500 a year over the births; and with an increasing ratio, this decimation will work the extinction of the race in a quarter of a century. European, but more especially Californian enterprise, already sways the development and the institutions of these islands, and the proximity and unequalled energy of our Pacific States must inevitably draw them at no distant day under the protection, if not the possession, of the Union.

New Base for Artificial Teeth.—Dr. G. F. J. Colburn, of Newark, N. J., has invented a substitute for rubber in dentistry, which promises to be of much value to the profession. It is in reality a cement of which mineral asbestos is one of the ingredients. Asbestos is a very peculiar substance. It is exceedingly light, and so very fibrous in its nature that it may be spun and woven like cloth, in which condition it resists fire, water, and many of the acids with complete success. Taking advantage of these natural qualities, Dr. Colburn has, by long study, discovered additional substances, which, when united, form an artificial base that possesses remarkable toughness, adherence, strength, and lightness. The ease and freedom with which it can be moulded is a strong recommendation. It can be readily applied to gold, platinum, and other plates. We have seen some full sets of teeth on aluminum plates that were truly beautiful. This new base contains no ingredients injurious to the health of the mouth or system. It is not affected by acid secretions, is free from all taste, and is inodorous.—*Scientific American.*

Remarkable Preservation of Beef.—Some beef which was deposited in tins beneath a heap of stones in Spitzbergen, by Capt. Parry, in 1827, was recently discovered, and a portion was cooked and eaten at a supper in Stockholm, after being preserved for forty years.

A New Method of Vitrifying the Surface of Iron has recently been introduced in Paris. Instead of covering the surface of the iron, according to the usual method, with a very fusible glass in powder and then bringing the iron to a red heat, the materials of the glass are laid upon the iron, which is heated until perfect vitrification takes place. The consequence is that the iron becomes oxidized, and combining with the silicic acid, the iron and glass form one substance. The coating may be as thick as desired, but it is found in practice that a thick coat of glass soon breaks away, while a thin one lasts for a long time. The method is being applied or tried upon armor plates for ships.

The Legion of Honor.—It is calculated that 64,000 persons wear decorations of the Legion of Honor. What chance is there for being *distinguished* in such a crowd?

Decoction of Sage in Profuse Sweating.—M. Vignard, of Nantes, after the manner of Van Swieten, has successfully employed decoction of sage for the relief of profuse sweating. In the case of a man twenty-five years of age, who had suffered, from time to time, during many years from attacks of this kind, the remedy proved effectual. The sweating began suddenly between two and three o'clock in the morning all over the body and was so profuse as to completely saturate the bed-clothes, and to a considerable extent the mattress also. In consequence of the regularity of the attacks, sulphate of quinia was tried as an antiperiodic, but unavailingly; the perspiration regularly reappeared, and without any apparent pathological cause. At length M. Vignard prescribed the following preparation: Take of chopped sage leaves a large teaspoonful (*une forte pincée*); of water, six fluid ounces. Boil the sage for a minute or two in the water; let it stand to cool, then filter and sweeten to taste. From that time the perspiration ceased whenever the decoction was taken, but reappeared when it was omitted. M. Vignard suggested the use of this remedy in the colliquative sweating of phthisis.—*Journ. de Méd. de Nantes.*

To Beautify the Teeth.—Dissolve two ounces of borax in three pounds of boiling water, and before it is cold add one teaspoonful of the spirits of camphor, and bottle for use. A tablespoonful of this mixture, mixed with an equal quantity of tepid water, and applied daily with a soft brush, preserves and beautifies the teeth, extirpates all tartarous adhesion, arrests decay, induces a healthy action of the gums, and makes the teeth pearly white.—*Ex.*

A Cheap Glass-Cutter.—The *Druggists' Circular* gives the following description of a cheap glass-cutter: —Take an old three-cornered file, heat it red hot, and plunge it into a previously prepared mixture, of equal parts of snow and salt, stirring it about so as to cool it as quickly as possible. Then grind the point on a wet stone, preserving the three sides as nearly as possible, and it is ready for use. Lay the glass to be cut on a perfectly smooth surface, apply a thin flexible rule, and draw the point of the file quickly over the glass. A litttle practice will teach one how hard to bear on without fracturing the glass. To insure success it is needful to notch the edges of the glass at the extremities of the scratch. The file can be reground when it becomes dull. Such an instrument will doubtless be found serviceable for cutting glass in the laboratory, and may be used as a good substitute for the diamond, and all ordinary purposes.

Students in Germany.—There are about 2,500 students of medicine in Germany, exclusive of Austria and Bohemia.

Original Communications.

SEA-SICKNESS.

OBSERVATIONS AND DEDUCTIONS FROM PERSONAL EXPERIENCE.

By WM. MASON TURNER, M.D.,

PHILADELPHIA.

An article by Dr. Armand, in the *Gazette Médicale de Paris*, suggested the following remarks:

A good deal has been written on this complaint, which for several reasons we might designate as singular. For many years it has been noticed. The *nausea navigatium* of the Latins, the *mal de mer* of the French, the *seekrankheit* of the Germans, and the *mareo* of the Spaniards, all correspond to our *sea-sickness*, and has been written of in as many tongues as above given. The grand point which has been discussed, and which is at issue now, concerns the *cause* of the affection. The answer seems ready enough to any question of this nature. It appears very natural to say that the cause of sea-sickness is—the *sea*, of course! There is truth in the answer, of a verity; and yet that answer may be forced to mean almost anything; for instance, that (1) sea-sickness is occasioned by the *sight* of the sea; (2) by the *peculiar odor* arising from the sea-water; (3) by the *calmness* of the sea; (4) by the *pitching* of the sea; (5) by the rolling of the sea, and so on, *ad infinitum*, or *ad nauseam*, at least. On many of these circumstances, or peculiarities, it has indeed been contended, depends the true cause of the sea-sickness. The distressing phenomena of the complaint are known either by experience, by sight, or by hearsay, to almost every one. It is useless to say anything on that head. It has been known, in some instances, to produce death by its violence, by occasioning hæmatemesis, by rupturing aneurisms, and by producing abortion in cases of advanced gestation; of course, the fatal results here being the effect of the violent effort to vomit, and the collateral forces called thus into action. The *cause*, however, as I have mentioned above, is chiefly deserving of interest, as it regards sea-sickness. It has been stated as different by a dozen different authors. At one time it was thought to be the specific odor arising from salt water, or an absence of the peculiar atmosphere which floats over the land. Again, for a long time, it was considered to be the unnatural motion imparted to the viscera of the abdomen and to the stomach, occasioning them to rub against each other, thus producing the nausea. Again, it has been contended that it is owing to an improper or irregular circulation, which leaves the brain badly irrigated. The grand nerve-centre being thus deranged, the stomach, by the intimate relation it sustains to it, is secondarily affected through the sympathetic system, and we have the result—nausea and vomiting. Some have explained sea-sickness by comparing the fluids in the body, so far as ascent and descent are concerned, to the mercurial column of the barometer, *i.e.*, that the body being unnaturally placed—thrown or tossed about, as is the case in swinging—the blood has an unwonted tendency to the brain, on which it presses, impairing its functions; then, secondarily, the stomach partakes of the derangement, and we have nausea and vomiting. Yet, again, it has been argued that *perverted vision*, occasioned by unusual impressions produced on the brain through the retina (I mean through or by means of the retina as the medium), is the true cause of sea-sickness. Dr. Armand espouses this view *in toto*. It was that feature in his article which arrested my attention, and made me at once condemn his position as untenable. Such I can readily prove it to be. To this, however, I will come anon.

So far as regards the odor theory, very little need be said. We have undeniable facts to prove this cannot be the cause. Some of our fishermen who live on Cape Cod have their houses so near the waves of old ocean, that the spray dashes into the doors. Here we have every odor from the sea which it is possible to have; saline incrustations cover everything, and the atmosphere is what might be termed *excessively marine*. What effect is visible in the inhabitants? Nausea and sea-sickness? No! rosy cheeks and hardy frames.

There is truth, however, in the theory of the unnatural motion imparted to the abdominal viscera; and, likewise, in regard to the opinion that sea-sickness is occasioned by an inequality of the circulation which leaves the brain impoverished. The barometric-mercury-column solution is not now generally received, and for good reasons. How could the theory prove true in practice, in regard to persons who occupied a horizontal position throughout the voyage, in which case the blood pressure on the brain amounts to nothing, or almost nothing?

It is with Dr. Armand's view, however, that I have particularly to deal, that of tracing sea-sickness simply to *perverted vision*. For the sake of doing him full justice, I quote the Doctor's words: "In some people it (sea-sickness) is produced if they *look* out of a carriage at the sides of the road and *watch* the trees, apparently in rapid motion."

I have italicized the words "look" and "watch" to call attention to the fact that the Doctor has the vision intimately concerned. Again: "All these circumstances, including *sailing*, have this in common, that they give rise to an interference with the laws of *perspective*, produce *perversion of vision*, cerebral fatigue, and a whole series of sympathetic phenomena, reacting from the brain upon the stomach and the entire organism. A proof that the fatigue of the *eye* is, in these cases, the chief cause of the peculiar feeling is, that after having waltzed, the most certain means of getting rid of vertigo is to *shut the eyes* for an instant; while on board ship a pretty sure means of avoiding sea-sickness is to *look* steadily on one point; a better still is to lie down and *close* the *eyes*."

The italics in the entire quotation are mine. From the extracts given, the Doctor's views are manifest. His grounds can be soon rendered untenable. I have, myself, seen considerable experience on the Atlantic, Mediterranean, and in St. George's Channel. During my voyagings I have experienced weather such as *old salts* say they never saw before, and never desire to see again. In storm or calm I paid a strict attention to sea-sickness, endeavoring to determine on some particular and certain cause for it. I am pretty well prepared to speak of it, both from observation and experience.

In May, 1859, I sailed as surgeon in the American packet ship "Admiral," from Havre in France, to New York. During the voyage I took especial pains to note the amount, the degree, and apparent cause of the sea-sickness, of which there was much throughout the passage, and to observe, particularly, the peculiar state of the patient, as regarded the respiratory organs, digestive apparatus, etc. From summings up in my note-book I learned the following when I arrived in New York. 1st. That, in the calmest weather, so far as the *sea* was concerned, no matter how great our rate of speed (and we frequently had fine breezes, while the sea was smooth) *there was less sea-sickness*, showing that impressions made on the corpora quadrigemina through the medium of vision, by passage through the water,

had no effect. 2d. That the worst sickness, and most of it, we had when the ship was laying-to, against head-winds and head-seas, and when she was alternately pitching in the chops and rolling in the troughs of the sea. This was when we were motionless, so far as regarded onward progress, and our only motion was an undecided, reluctant, very slow drifting to leeward, attaining, perhaps, the rate of a quarter of a mile in an hour, a speed which would not "pervert" the "vision" by any means, and could not, for the poor emigrants were huddled together in the "'tween-decks" of the ship, below water-line, where at mid-day the apartment is as dark as at midnight. The vision could not be perverted in this case, and could not have occasioned the sea-sickness. 3d. Again, in perfect calms, as regards the winds, when the ship did not even have steerage-way on, when a long, sullen, lazy roll was on the sea, the remnants of a late gale, sea-sickness was ever on the increase, though not so bad as in a chopped sea, as noticed above. This was the case when we were crossing the grand banks of Newfoundland Sometimes, in this latitude, the breeze died away so completely that we fished. The vision was not perverted here, no more than when we stand on the beach at Cape May or at Newport. 4th. In regard to the patients, I observed that those most affected had crammed to surfeiting their generally healthy stomachs with every kind of food before coming aboard. This point was particularly noted. Again, those persons who, presuming on the strength of their stomachs on land, had dared to go to sea on such presumption, were most often and speedily laid low. On the other hand, those whose digestion was bad on land and on sea, who had been suffering for some time with liver or general dyspeptic complaints, were most exempt from the malady. From this it might be inferred, generally, that those who were in ill health were least liable to sea-sickness, by reason of the already unsusceptible state of the stomach, liver, or brain, the latter perhaps primarily This leads, very naturally, to what I consider the most tenable reasons given for a certain train of circumstances causing sea-sickness. I will defer this, however, yet a moment.

In refutation of Dr. Armand's propositions or conclusions concerning perversion of vision causing sea-sickness, I have brought illustrations *au contraire*. First, in observation (1), where swift passage through water, in calm seas, with good winds, produced the least bad effect; and secondly, in observation (2), when in a heavy gale, chopped sea, and vessel laying-to, when all the emigrants were below and *out of sight* of everything; in other words, where vision was not called into play at all, there was most sea-sickness. More than that—and I am indeed thankful to be able to report this particular point—there was a man aboard the "Admiral" who was entirely blind, having a hard cataract in one eye, and corneal opaqueness complete in the other; a man who had not seen for twenty years—who could not tell day from night—yet that man was violently sea-sick for thirty-eight days; in fact, from the time we left the "Channel" until we made Sandy Hook. "Perverted vision" with a vengeance! Again, how can it be possible that perverted vision could have occasioned sea-sickness in one who kept the state-room and the bed from port to port? I hold just such a case now in my memory. A lady, on the French steamer "Meandre," was sea-sick from the time she left Marseilles until she landed at Alexandria, in Egypt. Yet she never stirred from her state-room, which was below the saloon-deck, and where there was no light scarcely, which she avoided altogether by closing the dead-light and foregoing the use of the lamp. So much, then, for Dr. Armand's *fatigue of the eye* and *perverted vision*, which to a blind man and to a woman shut up in what might be termed a "black-hole," is somewhat out of the ordinary path of logic,

From careful observation, I attribute sea-sickness simply and entirely to the peculiar motion of the ship, which motion affects, by deficient circulation, chiefly both brain and stomach—it matters not which first. Moreover, I think it attacks especially persons of a healthy organization, the more so where the viscera, as the stomach, has just been imposed upon, and tampered with. Generally speaking, we must conclude that the stomach is primarily affected by the unwonted motion, and that the dizziness, headache, etc., are secondary and dependent. We all know when we strike a person over the epigastrium, the blow will occasion vertigo, and sometimes complete unconsciousness. If we strike the same person a blow on the head, vomiting ensues as in concussion. This shows an intimate relationship, or, as a Frenchman has said, the *existence of two brains*.

It is very true that waltzing, and riding backwards in a carriage, will frequently produce in certain persons a nausea, approximating to sea-sickness. I think both are due to the same cause. In waltzing there is a wheeling around, an unnatural motion which throws the brain and other viscera into abnormal positions, hence the effect. In this case it cannot be denied that the confused blending of so many objects hurriedly and promiscuously together on the retina tends to increase this feeling. But at sea these objects are not present to blend together; there is nothing outside the ship save the limitless sky and water, a stray blackfish, an occasional swarm of Mother Carey's chickens, and a solitary gull! As to riding backwards, I speak this much from experience: When shut up in a close carriage and jolted over a rough road, I am sick at the stomach—virtually *sea*-sick, and it matters not whether I look out of the carriage window, or keep my eyes closed. This effect is not produced when I am on a smooth road. Many times have I rolled in a carriage over the gravelled drives in the Bois de Boulogne, near Paris, and, although going backwards, I never experienced any sickness at the stomach. It might well be asked here, if vision is at fault in riding backwards in a carriage, why is it that persons are less apt to be sick in an *open* carriage, where vision is not obstructed? Why, again, is it that those who are made sick by riding backwards in a carriage are never, or seldom at least, affected when riding backwards in a rail-car. I am an individual example as regards this point also. I have travelled backwards in American, French, English, German, Italian, Swiss, Austrian, and Egyptian rail-cars, where one-half of the passengers, from the peculiar construction of the carriages, *must* ride backwards; yet I never saw, in this experience, a case of perverted vision, with its consequent nausea. We never hear of a person being sea-sick on a river steamer. Who was ever thus affected when steaming up the Hudson or down the Mississippi? Yet the vision has certainly every *inducement* to become confused. We often see the sailor made sick when he first goes ashore from a long cruise. He is accustomed to tread his decks, to the ceaseless roll of the ocean. On land he *forgets* this peculiar (*his* customary) mode of perambulation; he raises his foot and lists to port and starboard, to windward and leeward, expecting, from habit, to be met half-way, but he misses stays and is soon abeam-ends, for the ground is a fixture. Vision is not here at fault, but the man *is sick*, and we know why. As regards the cure of sea-sickness, little can be done. The different viscera *must be habituated* to their unnatural motion and to the inequalities of circulation thus produced. A good plan is to wear a broad bandage tightly around

the abdomen and stomach, and try to "*tough out*" the sickness by braving the weather, and in storm or shine keeping the deck and learning to walk it. Lying down amidships *relieves* sea-sickness. So far as remedies (medical) are concerned, calomel, citric acid, the fluid extract of valerian, and the oxalate of cerium have been recommended.

The advantages resulting from sea-sickness are positive and negative. Sometimes the agonizing efforts to relieve the stomach occasion, as remarked before, a hæmatemesis, and fatal results have occurred in advanced pregnancy. Moderately, however, sea-sickness acts beneficially by exciting the liver to more vigorous action, and by causing the stomach to eject surplus bile. More than that, it eventually tones the appetite and leaves the bowels in a good condition by the increased peristaltic movement imparted. As Dr. Chapman, I think, was accustomed to say, "It shakes up the gall bladder, and clears the ship fore and aft."

I hope my remarks as regards this theory of perverted vision may not appear egotistical, nor do I plead guilty to the charge of hypercriticism. My remarks are based on the teachings of the great master—experience.

CLINICAL PAPERS ON EAR DISEASE.

By D. B. St. JOHN ROOSA, M.D.,

PROFESSOR IN THE UNIVERSITY MEDICAL COLLEGE.

NO. I.—INSPISSATED CERUMEN.

It is intended, in the papers which are proposed under the above title, to present some of the practical results of an experience in ear diseases, reaching over quite a large number of cases, in such a way that they may be useful as a guide to those who see comparatively little of the diseases of this organ.

Among the laity, and even in the profession, hardening of the ear-wax is regarded as quite a common and harmless affection. All forms of deafness are ascribed to this cause, and the first treatment that many ear patients receive, is a vigorous syringing, to see "if the wax be not hardened," and this often without any preliminary examination. Impacted cerumen is indeed quite a common occurrence, but it is by no means as simple an affair as has been generally supposed. I do not mean by this, that it is anything more, as a general thing, than a local affection, but as such, it may produce results very detrimental to the function of hearing. It hardly seems to occur more frequently in persons with a soft skin than others, as has been suggested by some authors, for among the patients whom I have seen, careful examination has failed to detect any such origin. Persons with a dry and harsh skin have as often come to me with impacted cerumen, as the opposite class. A frequent cause is the too careful washing of the auditory canals with soap and water, which some over-clean persons delight in doing. This rinsing out the canal plugs the natural yellow wax, which is on its way out, down to the bottom of the canal, and being continued morning after morning, at last fills up the ear, and when the drum is once fairly covered, and pressed upon, and *not till then*, deafness results. It is somewhat remarkable how long persons may have the ears plugged up with hard wax without being aware of it. On examining patients who present themselves with impacted wax, only causing deafness on one side, we will nearly always find the same condition of things as to the wax, in the other ear. If the cerumen be very black and hard, and if it comes out in one large plug, we may conclude that it has been there for years. I recall two cases in which, from definite accounts, we could safely conclude that five years had elapsed since the deafness occurred. In both of these cases the hearing became normal after the wax was removed. Impacted wax sometimes causes serious inflammation of the canal and drum. In one case, that of a young lady, suppuration of the drum resulted from hardened wax pressing upon it, and the wax was removed spontaneously like a shot from a pistol, and, as was stated, with almost as loud a report. This evacuation was preceded by the most intense pain. The removal of a plug three-fourths of an inch long from the other auditory canal, and which was wedged in very tightly, saved the patient from the inflammation which was so troublesome on the other side. In another case still under treatment, what was supposed to be on first examination a plain case of inspissated cerumen, was found, after removal of the wax, to be one of inflammation of the integument which lines the canal. The removal of the hardened wax was, as it were, only the removal of a huge scab from an ulcerating surface. I have seen other cases like this.

Inspissated cerumen causes many symptoms. The prominent ones are:—

1. Sudden deafness.
2. Tinnitus aurium.
3. Vertigo.
4. Earache.

Of course an examination is the only method of clearing up the diagnosis. This examination should be undertaken with the ear mirror (or otoscope, properly called), and not with the syringe. In other words, it should be ocular and not tactile. The trouble can hardly be confounded with any other affection. Wax which presses upon the drum is almost always black, not yellow, and nearly fills the canal. No decided prognosis can be given from seeing the wax, as to whether its removal will restore the hearing. Hardened cerumen very often forms over a perforated or ulcerated membrana tympani, and is then of course only a small part of the disease. It often results also from the dropping of oils into the ear for some therapeutical end seldom attained. The original disease for which the oils were used was then probably an affection of the cavity of the tympanum.

The habit of examining the ear in all cases with head symptoms, will sometimes assist materially in clearing up a diagnosis. I once cured a man from the effects of a supposed sun-stroke, by removing inspissated cerumen, who had been treated for two months in a hospital for cerebral disease.

Patients who have once had impacted wax, are apt to suffer again from the same cause, at least I have seen quite a large proportion of cases in persons who have been affected in the same way before. Such may be advised to have their ears syringed with a solution of bicarbonate of soda and water, about once in two months. The removal of the hardened mass is very often a tedious affair. I once spent an hour a day for a week in removing a mass from the ear of a lady patient. In the interim the best solvents, such as soda, were used. With previous soaking the canal with a warm solution of soda, say a drachm to the half pint, ten minutes will generally suffice to remove the mass. A good india-rubber syringe, holding at least four ounces, should be used, and the auditory canal well straightened by holding up the auricle with the left hand, at the same time syringing with the right. The glass syringes are of no use. The stream sent in should be vigorous but steady, and care taken not to inject it with such force as to cause pain or dizziness. There should never be any pain caused in syringing the ear for any purpose. Where pain is produced, syringing will do harm. A thin bowl is held under the ear by the patient. No assistant is needed.

No towel need be placed on the patient's neck, for with careful manipulation no water will be spilled.

The ear may contain an astonishingly great quantity of hardened ear wax, and an examination should be made very frequently during the course of the syringing to determine when it is all removed. No after-treatment is necessary. If, however, sounds are oppressive, as they often are, after the removal of large quantities of ear wax, a little cotton may be worn in the meatus for a day or two. The membrana tympani always appears reddened immediately after the removal of the cerumen, and then dull. It will be some days before it regains its normal translucency. If the hearing be not improved immediately on removing the wax, the middle ear should be inflated by Politzer's method. The drum is sometimes sunken in temporarily, and one or two passages of air through the eustachian tube will restore its position as well as the hearing.

Professor Gross recommends the use of a pick for the removal of impacted wax. This does very well as an aid where the wax is very hard. If it be used, the surgeon should have a mirror on his forehead, and never put the pick in the canal, unless he can see just what he is doing. Painful and even destructive inflammation may be caused by this mining out process. The general practitioner, to whom ear cases come in only a small proportion in his daily rounds, had much better rely on the use of a syringe and warm water where possible, having previously moistened the canal with a warmed solution of soda, zinc. sulph., or with glycerine and water, sweet oil, etc. Inspissated cerumen rarely occurs in children. I suppose there is no difference in the liability of the sexes, and I know of no well-established proximate cause, except the one given in the beginning of this article, *i.e.*, packing the meatus by the frequent pouring in of water. Yet we might say that it is common for hardened wax to collect about a foreign body in the ear, such as a raisin, introduced originally to relieve earache, a cherry-pit, etc., but here the inspissated cerumen is only a concomitant. It is hardly to be credited, although formerly generally believed, that a diathesis has anything to do with it, or that there is any disease of the ceruminous glands. The cause is probably in one way or another mechanical—that is, there is some interference with the normal and daily removal of the secretion.

HERPES CIRCINATUS AND FAVUS FROM ACHORION IN THE MOUSE.

By R. CRESSON STILES, M.D.

Two specimens have accidentally fallen under my observation, within a few years, of mice infected with a vegetable parasite which had destroyed the scalp, blinded the eyes, and covered the head with whitish friable masses of fungus. Such specimens (similar at least in general appearance) I find, on inquiry, are not rare.

Under the microscope the fungus in question presents the characters of Achorion Schœnleini; its elements are merely smaller, or less luxuriant than those taken from a crust of favus on the human scalp.

Recently I inoculated a spot on my forearm, as in vaccination, with a fragment of the favus-crust of a mouse, and in ten days, when I had supposed the inoculation a failure, a ring of herpes circinatus made its appearance, of a quarter of an inch in diameter, around the point of inoculation. The ring of vesicles continued to enlarge until it reached an inch in diameter, the enclosed area regaining the natural appearance of the skin. Under the microscope, however, its epidermic scales were found increased in size; many of them containing a formidable nucleus and nucleolus as in chronic eczema.

Attached to the scales of epidermis were spore-bearing filaments and spores, the latter rapidly multiplying by gemmation. The circle of vesicles was composed of minute acuminated elevations of the cuticle, filled with a clear lymph containing cytoid corpuscles only. At their base were found filaments of mycelium, but no spores. The vesicles are, without doubt, produced by the irritation of these filaments as they extend in the (so-called) rete mucosum.

A single application of an emulsion of the strongest carbolic acid (from deliquescent crystals), with an equal quantity of water, caused the whole disk to come off in a single scale or crust, in about a week, and the disease did not reappear.

Finding the results of this inoculation so readily controlled, I repeated the experiment on two of my medical friends, who were sufficiently interested in the matter to be willing to lend themselves to its further investigation. In both the period of incubation was ten days. On one no herpes appeared, but instead, the hair follicles became the seat of porrigo favosa. On the other, herpes circinatus first appeared; but after the herpetic ring had reached an inch in diameter, pits of porrigo favosa occupied its area, a hair passing through the centre of each. The whole area was elevated, congested, and its epidermis abounded in the filaments and spores of the parasite.

The results of this last inoculation gradually disappeared under the frequent application of carbolic acid.

In connection with the pathology of favus, the researches of Schœnlein, Gruby, Remak, Lebert, Bennett, Bazin, and Robin possess an interest inseparable from successful endeavors to trace the mode of action of a palpable, material cause in the production of a disease, the nature of which had long been the subject of surmises and theories only. In experiments on the inoculation of the achorion from favus in man, favus only, as far as I am aware, has been produced; and it has not been suspected that herpes circinatus and porrigo favosa were but different modes of growth and activity of the same living germs. Yet favus has often been seen to follow herpes, and the coincidence of the two diseases in the same person is quite common.

Recently Tilbury Fox has published an account of experiments on the production of herpes circinatus from favus in the cat. The source of favus in the cat is most probably the same disease in the mouse. The pulverulent crust of favus in the mouse scatters its fragments on the slightest touch, and articles of clothing are thus liable to the infection, and readily transmit it to man.

The value of carbolic acid in destroying a parasite so tenacious of vitality, is an indication of the importance of this agent as a parasiticide and disinfectant.

DELIRIUM TREMENS SUCCESSFULLY TREATED WITH COFFEE.

By WM. R. WHITEHEAD, M.D.,

NEW YORK.

Recently, in a case of delirium tremens, I observed a peculiarly marked tranquillizing effect caused by strong coffee, and which produced prolonged and refreshing sleep, after the usual remedies had proved ineffectual.

Mr. C., a merchant, visiting New York on business, who had been drinking very hard for several days, was taken with delirium tremens on the 13th of last March. His friends stated that they believed this to be his first attack. He was seen by a physician on the 15th, but did

not receive further medical attention until the night of the 17th, when I was called to see him. He exhibited the usual symptoms, with the exception of a remarkable absence of muscular twitching on feeling the pulse. His hallucinations were at times very amusing; he was not disposed to be violent, but was quite tractable and easily controlled by his attendants. A mixture, containing about a drachm of chloroform to the dose, was prescribed to be taken every few hours.

The next morning he was more quiet, having slept about two hours during the night, and for the first time since his illness. The condition of his bowels, his urinary and other secretions, were carefully observed. His tongue was large, white, and moist. Some pills of opium were substituted for a mixture containing chloroform and tincture of hops, ordered early in the day. A small quantity of ale was permitted, and some beef-tea and chicken-broth ordered. At night he was very restless; his pulse at one time could not be felt; his extremities became cold and respiration labored:—I gave him half a glass of whiskey.

On the morning of the 19th I was told that he slept an hour or two soon after drinking the whiskey; his skin was jaundiced, and he was costive. Twelve grains of blue mass were prescribed, which failed to produce the desired effect. At night eight grains of calomel were given, to be followed in the morning by a clyster. He vomited several times during the day, but retained the nourishment which he had taken.

On the 20th his bowels were slightly relieved, his skin was moist, and pulse good. I prescribed sulphate of morphia in half-grain doses; he became quite restless during the day.

The next day there was no sensible abatement of the restlessness, and he was not free for any length of time from ludicrous or disquieting hallucinations. At no time, however, was he violent, nor did he manifest great fright. The sulphate of morphia was repeated; he took some nourishment; his bowels were moved with a clyster. Complaining of soreness in the stomach; a blister was placed on the epigastrium.

On the 22d, at the morning visit, being satisfied that the morphia had failed to afford relief; bromide of potassium was given, twenty grains at a dose, every two hours, in a suitable mixture. At the third dose he became more restless and excited than he had previously been. The bromide was discontinued, and three subcutaneous injections of Magendie's solution of morphia were made, of thirty drops each, at an interval of one hour between each injection. They failed to produce the slightest apparent effect. He drank half a glass of whiskey, which seemed to quiet him considerably. He took frequently during the day Tourtelot's beef-essence with much relish.

On the morning of the 23d I was told that after drinking the whiskey he slept three hours, but I found him quite restless. Bromide of potassium was prescribed in drachm doses, of which he took two, each at an interval of two hours. At half-past four P.M., he was much more quiet. He asked for a cup of coffee, which he drank very gratefully, and at the same time eat a small piece of bread. Ninety grains of bromide of potassium were ordered at a dose, in which doses I was reliable informed it had been recently given successfully in delirium tremens at the New York hospital:—During the night two doses of the bromide were administered. His urine was abundant and clear; pulse strong and full. He slept about an hour that night. The next day his bowels were slightly moved with a clyster. The bromide of potassium was repeated twice, in doses of ninety grains, and produced at the second dose some anæsthesia of the skin.

On the 25th Professor Willard Parker saw him with me, and observed the same absence of muscular twitching to which I have already alluded. It was decided that the patient should have his body and limbs well rubbed after being washed; that he should be permitted to have a cup of coffee, and as much nourishment as he could be induced to take. At night a hot whiskey toddy was to be given to him, to be succeeded by inhalations of ether, but the ether was not given.

At the morning visit the next day I found that he had not slept during the night, and was very restless. The toddy seemed at first, as his nurse informed me, to make him more quiet; but he soon became much more restless after than before taking it. Chloroform, opium, brandy, and bromide of potassium had been each unsuccessfully essayed; the last of these substances in such doses as thoroughly to test its action. One prominent idea, however, governed my course throughout the treatment—it was properly to nourish the patient. I regarded the alcohol as a poison to be eliminated, but considered that the equilibrium of the nervous system should be gradually reëstablished by suitable stimulants. Only temporary benefit resulted from the remedies used; and if at times they failed to produce any appreciable good, they, on the contrary, once or twice seemed to be productive of harm. When quiet, and sleep did not immediately follow the use of brandy, the restlessness was much increased. Morphia appeared to be positively injurious. The bromide of potassium, in doses of twenty grains, greatly excited the patient; increased to drachm doses, and then to doses of one drach and a half each, made him a little more quiet. I was not encouraged, however, to continue any longer these remedies, but disposed to discontinue further medical treatment, and rely upon the gradual assimilation of concentrated and nutritious food, to allay the nervous excitement, and produce sufficient recuperative sleep.

The patient had several days before expressed a wish for coffee, which he seemed to relish. It now occurred to me that coffee, acting as a food, containing nitrogenous principles, and also as a special nervous stimulant, might in this case, by its peculiar action, if given in sufficient quantities, produce a quieting effect and induce sleep. Consequently coffee was tried; and the issue of the experiment proved to be successful.

At two o'clock P.M. about a pint of very strong coffee was prescribed, with a little cream, enough to make it palatable for him; and a broiled steak ordered, a part of which he eat. At eight o'clock P.M. I found that he had slept four hours. He drank again a large cup of coffee, and took fifteen grains of blue mass.

On the 27th, at the morning visit, I found that he had slept nearly all night, but was then restless. His bowels had been moved, and his general condition was very much improved. Very strong coffee was again prescribed, and at half-past twelve o'clock P.M. I found him asleep. After this the coffee was repeated a few times; he continued to improve, and soonrecovered.

Probably this nervous stimulant, by imparting an increased tone of a peculiar character, to the general system, reëstablished its equilibrium and caused sleep, when other stimulants, acting in a different manner, failed to produce this result. This, however, is merely a conjecture, and may possibly be explained by others in a more satisfactory manner.

Creosote for Burns.—A correspondent highly extols creosote as an external anodyne for burns.

Reports of Hospitals.

JEFFERSON MEDICAL COLLEGE,

OF PHILADELPHIA.

SURGICAL CLINICS OF PROF. GROSS.

CATARACT.

OCT. 27, 1866.—Mrs. Catharine H——r, æt. 47. One eye of this patient was operated on a year ago, and there still remains in it a portion of the capsule of the crystalline lens, presenting a dense, white, chalky appearance, as observed through the dilated pupil. There is some amount of vision. In the other eye there is a cataract of the crystalline lens and its capsule, which has existed about eighteen months. The general health of the patient is good; she has no diabetes. Three of her brothers have gone blind with cataract.

Occasionally as many as five or six members of the same family suffer from the disease, showing that there is a hereditary or family proclivity to the affection, though this is, of course, uncommon.

Cataract is an opacity of the crystalline lens and its capsule, or of the crystalline lens alone, or of its capsule alone. It presents itself in various forms or degrees. When the opacity pervades the entire crystalline lens and its capsule, we say the cataract is complete or mature; it is imperfect when the reverse is the case,—when there is a portion of the crystalline lens, or of its capsule, or of both, in a state of transparency or partial transparency. Cataract is liable to occur at all periods of life; it is sometimes an intra-uterine affection, the disease taking place before birth, during gestation; or it may take place soon after birth; it is uncommon in children and in very young persons, being met with most frequently after the age of fifty, and from that on to sixty-five or seventy years. It generally comes on without any assignable cause, and is developed gradually, not suddenly; but there is occasionally an exception to the rule, as in a case which occurred to the speaker many years ago in the Louisville Hospital, where a man's eye became cataractous in the course of twenty-four hours.

The disease is liable to occur in both sexes, but is more common in males than in females, in all probability growing out of the usual difference of their daily employments. It is liable to occur in persons of all ranks and of all pursuits; it is said that persons who use the eye a great deal for minute vision are more liable to suffer from it than others, but it is not determined that this is the fact. It was formerly said that blacksmiths were exempt.

The disease is a painless one; the loss of sight is gradual, and, when there is no complication attending the case, there is still a certain degree of vision when the pupil is dilated, as in cloudy states of the weather, or in daylight when the pupil has been dilated with atropia, belladonna, stramonium, or some narcotic of this kind. Under these circumstances the rays of light pass between the margins of the iris and the retina so as to produce a certain amount of vision. When there is adherence to the margins of the iris, the rays cannot penetrate and the patient is completely blind.

The opacity of the cataract generally begins from the radius to the circumference. Simultaneously the opacity begins in the capsule and the lens, and begins usually in the posterior portion. When the opacity is in progress we can discern it very readily by looking through the pupil, especially if previously dilated, as a little speck of a whitish, or slightly yellowish, or drab-colored aspect. This enlarges, gradually increases, and when the cataract is complete there is no difficulty at all in regard to the diagnosis. Sometimes, but very reprehensibly, opacity of the cornea is mistaken for cataract, but this is the result of inflammation, and should be duly recognized. Cataract is an opaque body lying behind the pupil directly in the centre of the eye. When there are adhesions of the iris to the lens, or when the pupil has been diminished in consequence of inflammation, and opacity of the cornea coexists with these adhesions, then the diagnosis may be very difficult indeed. Under all circumstances the proper plan is to dilate the pupil by the application of atropia, the proximate principle or alkaloid of belladonna. From one-third to half a grain dissolved in half an ounce of water will be of sufficient strength for the purpose, and a few drops of this solution put in contact with the cornea and conjunctiva will dilate the pupil. The head should be thrown back, the eyelid opened to expose fully the surface of the ball of the eye, and then five or six drops of the solution should be put in contact with the organ, and if the process be repeated several times in the twenty-four hours, free dilatation will be the result, which will continue for several consecutive days. It dilates the pupil to the very utmost, paralyzing it for the time being. Instead of dropping the solution into the eye, it may be applied by rubbing the solution on the eyelids and eyebrow. We no longer use the belladonna as formerly, the atropia being more reliable, prompt, and efficacious.

When the pupil has been dilated we look at the cataract, and the diagnosis is sufficiently plain.

There are different operations in vogue for the removal of cataract. When the cataract is soft, when the disease is of recent standing, or occurs in a very young person, the operation adapted to its relief is comminution by means of the needle, or a very delicate knife introduced into its substance, passing the instrument about in different directions and breaking up the lens and its capsule, hashing it as it were, and subjecting the fragments to the action of the aqueous humor of the eye, or the absorbents of the eye, if you please, for it is a disputed point if the aqueous humor, weighing only five grains—a few drops of liquid—has any solvent powers or not. All we know is that when the cataract is carefully broken up in this way, and the resulting inflammation is properly kept in check, solution takes place, the fragments gradually disappear, leaving the aqueous humor perfectly clear and limpid for the transmission of the rays of light.

A soft cataract is usually distinguished by its large size and peculiar whitish or bluish appearance.

When the cataract occurs in a person of advanced life, is of long standing, comparatively small, of a yellowish or drab-colored appearance, then we assume that it is hard, and that the operation of comminution is not adapted to it, for we cannot break it up with a needle or comparatively sharp knife. It must be extracted.

Formerly, indeed until within the last few years, an operation called *depression* or *couching* was very much in vogue. This operation consists simply in introducing a delicate needle into the eye, and displacing the cataract or opaque body by throwing it out of the axis of vision and burying it in the vitreous humor of the eye, depressing, couching it, or laying it down as it were. This operation has become obsolete, and very justly so, because it has been found from long experience that this opaque body, the crystalline lens with its capsule, will remain here for years undissolved, unaffected by the vitreous humor of the eye; not only this, but it will dissolve the vitreous humor of the eye itself, by its pressure, by the inflammation which it produces; and it will gradually sink down to the lower part of the eye so as

to press upon the retina, and in this manner produce an amount of inflammation which will be rapidly followed by an irretrievable loss of sight.

There is another operation in connection with soft cataract, consisting in lineal extraction, devised by Gibson, of England, in 1811, subsequently modified by some German surgeons and revived afterwards in England. It consists in making a small incision, not more than about two and a half lines in extent, that is about one-fifth or one-sixth of an inch, through the lower part of the cornea, and then scooping out the lens along with its capsule. This is called linear extraction, because of the delicacy of the incision. It is adapted only to soft cataract, not to hard. The old operation consists in making a large free incision into the cornea, either in the upper or lower portion of its extent as the case may be, the lower incision being usually preferred, and very justly so. The incision includes fully one-half of the circumference of the cornea. It is done with a delicate knife, and the next step consists in lacerating the capsule of the lens; inthe next place pressing out or hooking out the opaque body, the crystalline lens. This is called the operation of extraction, and when properly performed affords vision at once. The patient has to run the risk attendant on the resulting inflammation, which may be so great as to prevent union of the wound in the cornea, and lead to gangrene or sloughing or destruction of the eye, as has happened in thousands of instances. It is adapted only to cases of hard cataract, and the eye should be rather prominent than otherwise; if it is sunken back in its socket it is not as favorable for extraction; nor is it well adapted where there is unusual flatness of the cornea, which should be convex, prominent, in order to justify this kind of interference; still, this is not an insuperable objection. Then there should be a perfect formation of the pupil; it should be dilatable, not necessarily dilated; there should be no adhesions at all, no disease in the iris—otherwise the case is not adapted for extraction.

The operation proposed to be performed in the present instance consists in lacerating the capsule, and those portions of the lens which can be brought under the influence of the needle. The cataract appears to be a soft one, or very nearly soft, though there may be a little nucleus in the centre. The operation is easy, the manipulations simple, and it is not painful. It is not necessary to administer chloroform, as is done when the operation of extraction is performed, when we want perfect control over the eye as well as over the body. The patient may sit up or lie down, as is most convenient, though it is preferable that the patient sit up, with the head reclining against the breast of an assistant. The upper eyelid should be held out of the way by the index-finger of the assistant, the lid being caught between the soft portion and the nail; the lower lid is depressed by the index-finger of the surgeon; then the delicate needle, held in the other hand as a writing-pen, is introduced and the cataract comminuted.

SEBACEOUS TUMOR OF NECK AND SHOULDER.

Oct. 27, 1866.—Lizzie R——o, æt. 22. This patient had a tumor of fourteen or fifteen years' standing upon the back part of the neck and shoulder. The skin was not particularly discolored, being but a shade or two more red than the parts around, owing to the pressure of the tumor on the skin and the consequent congestion of the vessels in that part. It was movable and painless.

There are various tumors liable to form in this situation; some formed from preëxisting tissues, others not. We have the fibroid tumor, a structure composed of fibres crossing each other in every direction, and imparting a firmness to the tumor unlike that found in any other portion of the body except cartilage, tendon, and bone; a tumor liable to become developed in many portions of the body, more particularly the uterus. In the case before us, the tumor is comparatively soft, therefore we exclude from our diagnosis the idea that it is one of those class of tumors fibroid or fibrous in character. In the next place, is it a cartilaginous, or fibro-cartilaginous, or bony tumor? Of course if it is too soft to be fibrous, it cannot be any of these. It is not a wen-like excrescence, as occasionally occurs in various parts of the body, especially the head and the face; so we exclude that from our diagnosis. It is not a nerve tumor or a neuroma, because it is free from pain and it is situated very superficially; besides, it is much larger than a nerve tumor would be in this situation. The nerve tumor occasionally acquires a large bulk, the size of a man's head, when it occurs in connection with the large nervous trunks. It is not a cystic or an encysted tumor; it is not as distinctly elastic as if it contained a watery or sanguinolent fluid. It is not a hydatid tumor, for it is exceedingly uncommon to find such a tumor under the skin, and then it is remarkably elastic, fluctuating distinctly under pressure. This tumor has a semi-elastic feeling, bordering on the doughy, difficult to describe.

Insertion of an exploring needle, however, demonstrated that this tumor was sebaceous or encysted. It was larger than the sebaceous tumor is usually found, and it is rare that a sebaceous tumor is found in this situation; hence the liability to a mistake in diagnosis.

On removal, the cyst of the tumor was much shrunken, its contents resembling spoiled tallow or lard.

This is therefore a tumor which had its origin in a pre-existing tissue, and is not a new formation, having been developed from a sebaceous gland, follicle, or crypt. The inspissated secretion which becomes pent up does not remain an innoxious fluid, but from long retention may become excessively offensive in consequence of the presence of a large quantity of sebaceous acid. Sometimes we find it partly fluid and partly solid; now and then cases occur in which hairs are found among the contents, especially in the congenital form of the sebaceous tumor, such as developed under the eyebrow, eyelid, forehead, and various portions of the scalp. They are frequently seen with numerous hairs in the interior of the cyst, evidently retained during the progress of development.

The cyst is nothing but the wall of the sebaceous crypt or follicle in a state of hypertrophy in consequence of long-continued interstitial deposits; retention of the fluid produces irritation, provokes a flux of blood and nerve fluid to the part, and thus the wall of the crypt becomes greatly enlarged, and in some cases, when the tumor is very old, a portion of the cyst degenerates into fibro-cartilage, or into cartilage, and occasionally, though very rarely, into bony substance. Thus this tumor is simply an unnatural development of a preëxisting structure, frequently so small it cannot be perceived by the naked eye, but capable, during the progress of its development, of assuming the volume of a hen's egg or an orange. This tumor does not take on malignant action, but in consequence of long-continued pressure, or the pressure of the dress on any part of the body where the tumor may exist, ulceration is liable to take place, and then a very unpleasant sore may be produced, causing pain, and being the seat of a constantly offensive or fetid discharge.

The only remedy is excision, and every particle of the cyst must be removed; if the slightest atom is left behind, it becomes the nucleus of a new formation.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

CALLED MEETING, SEPTEMBER 18, 1867.

DR. ALFRED C. POST, President, in the Chair.

THE QUESTION OF AID FOR THE YELLOW-FEVER SUFFERERS AT THE SOUTH.

DR. CHAMBERLAIN, in explanation of the objects of the meeting, read the following:

301 MOTT STREET,
NEW YORK, Sept. 14, 1867.

SIR: At a meeting of the Executive Committee appointed at a general meeting of citizens held on Friday, the 13th inst., to devise means for administering to the wants of the sufferers from yellow-fever, it was

Resolved, That, in the judgment of this Committee, it is desirable that the subject of ways and means to aid the sufferers from yellow-fever in the Southern cities should be taken into special consideration by the New York Academy of Medicine, the Kings County Medical Society, and other similar associations: and inasmuch as hundreds who now need our charitable relief daily become victims of this terrible scourge, prompt action is necessary.

Very respectfully, your obedient servant,
JOHN BROWNE, Secretary.

A. C. POST, M.D., President of the New York Academy of Medicine.

DR. HAMILTON, after adverting briefly to the destitution of the South, and the urgent want of experienced nurses, gave it as his opinion that the epidemic would spread, and that its final arrest could not be expected before the accession of frost, which in the Gulf States occurs about the middle or latter part of October. He said the medical profession, through its various organizations, was capable of wielding a power which had not yet been exerted, and which might well be put forth in a cause like this. It was not expected that members of the Academy would contribute largely, because in many instances they were not able to do so; but they could do much towards arousing a public feeling that would carry material aid to the sufferers. He then moved the following, which were unanimously adopted:

Resolved, That the President of the Academy, Dr. ALFRED C. POST, with the Council of the Academy, constitute a Medical Relief Committee, who shall be authorized to receive and distribute such funds as may, for the purposes specified, be handed to them, and that they be authorized also to adopt such further measures for the relief of the sick at the South as they shall deem proper and fit.

Resolved, That we recommend to all American medical organizations, especially in the States not suffering from the present epidemic, to take similar action as speedily as possible. The President and Council of this Academy will take charge of such funds as may be forwarded from other medical societies; or they may send their contributions direct to the President of the Howard Association at New Orleans, which Association will distribute the same to other branches in other cities in such manner as may be required.

THE PERILS AND THE DEVOTION OF THE ARMY MEDICAL STAFF.

DR. CHAMBERLAIN read a letter from Dr. E. Harris, calling attention to the devotion of the army surgeons in the South, many of whom have died at their posts during the prevailing pestilence, and offered the following resolutions, which were adopted unanimously:

Resolved, That this Academy sends its greeting of sympathy and cheer to our professional brethren of the fever-stricken South; that it recognizes with admiration their heroic and unselfish devotion to the profession and humanity; that in the swelling list of those who have not feared to die, and in the unfaltering ranks of those who live to labor in this good cause, the profession and the world are again called to witness that the true physician braves peril and gives his life whenever necessary in ministering to the sick.

Resolved, That we endorse and respond to their call for all personal and material aid needed for the most complete medical care of the sick.

The Academy then adjourned.

EAST RIVER MEDICAL ASSOCIATION.

STATED MEETING, AUGUST 6, 1867.

DR. VERRANUS MORSE, PRESIDENT, in the Chair.

AMENDMENTS OF THE CONSTITUTION AND BY-LAWS.

DR. WEISSE proposed several amendments to the Constitution and By-Laws, the chief of which related to the division of the organization into sections. These were as follows: Surgical Anatomy, Pathology, and Practice, F. D. Weisse, *Chairman*; Visceral Anatomy, Physiology, Pathology, and the Practice of Medicine, Alexander W. Stein, *Chairman*; Obstetrics and Gynæcology, M. S. Buttles, *Chairman*; Therapeutics and Medical Jurisprudence, Truman Nichols, *Chairman*; Hygiene, Climatology, Meteorology, and Vital Statistics, William F. Thoms, *Chairman*.

DECEASED MEMBERS.

DR. THOMS announced the decease of Drs. Philip O'Reilly and Edward Kelly Hogan. The following committee, at the conclusion of eulogistic remarks by several members of the Association, were appointed to draft resolutions expressive of the sense of the meeting:—Drs. W. F. Thoms, John Burke, and John Purcell; and Drs. Henry E. McCartin, E. J. Hogan, and James J. Purcell. On motion, the following were appointed a special committee on visitation of sick members:—Drs. William Newman, Truman Nichols, John Burke, Richard J. O'Sullivan, and Henry E. Crampton.

THE PRESENT STATE OF KNOWLEDGE REGARDING ZYMOTIC DISEASES.

DR. SKIFF, in a paper which he had prepared, briefly reviewed the substantial advances made in our understanding those diseases which nosologists had classed under the head of *zymotic*.

He maintained that zymotic disease depended for its cause on either *virus*, *miasm*, or *venom*, the first-mentioned of which would constitute the agent for the transmission of contagious diseases, *e.g.*, variola, which by virtue of the impalpable miasm diffused through the air or inherent in the fomites, was also an infectious malady. Miasm, or the second morbific principle, is that unknown, inappreciable emanation, exposure to which produces a specific disease. To illustrate, the same miasm will not produce, in different individuals, typhus fever, yellow-fever, and cholera. Venom differs from both virus and miasm; it is a physiological secretion found in the so-called venomous insects and reptiles.

He then alluded to the so-called infantile diseases,

which claimed so large a share of the attention of humanitarians and medical philosophers.

After commenting upon ventilation and cleanliness as being the most positive of prophylactics, he passed to the consideration of disinfectants, which for convenience of study were classed under three heads:

1. Chemical disinfectants.
2. Absorbents.
3. Antiseptics.

In the employment of all the practical applications of our art, we must as nearly as may be, conform to the sanitary processes of nature, whose principal hygienic operations were mainly oxidation, diffusion, and dilution. All these we may imitate, but only to a limited extent.

Keeping in mind that all other means are but subsidiary to thorough ventilation and removal of organic matters, the most effectual method of purifying the air and destroying the virus or infection of disease is by the evolution of certain gases, such as ozone, chlorine, hyponitrous, nitrous, and sulphurous.

Ozone may be liberated by placing a stick of phosphorus on an ordinary tea-plate, with sufficient water poured upon it to immerse two-thirds or three-fourths of it, according to the size or the volumetric capacity of currents of air circulating through the room. The evolution of this agent may be instantly suspended by covering the phosphorus entirely with water.

The next article in importance in point of practical efficiency is

Chlorine, which is less objectionable than the preceding, from the fact that there is less danger of mismanagement. The liberation of the gas is more gradual and more controllable. The formula used in the U. S. army hospitals is an excellent one, and is as follows:

18 parts common salt, finely ground,
15 " binoxide manganese, finely pulverized.

Mix, and place in a flask, and pour on it the following mixture, completely cooled:

45 parts of concentrated sulphuric acid,
21 " water. Shake the flask.

Bromine is very efficient; it evaporates spontaneously when the bottle containing it is uncorked, and soon deodorizes the infected room. But being difficult to manage, and expensive, it is less used than others.

Nitrous acid acts very powerfully on organic matters, but being very irritating to the respiratory organs, it it should only be used in the chamber after vacation by the patient, which of course is not always practicable. It may be evolved by placing nitrate of potash in sulphuric acid, or by placing a bit of copper in nitric acid, diluted with water.

Sulphurous acid, readily obtained by burning sulphur, acts very powerfully on organic matter by oxidation, especially destroying animal contagion and miasms, but is also irrespirable, except in limited quantities.

The agents just mentioned are deodorizants, and antiseptic as well as true disinfectants, by virtue of their oxidizing properties.

Absorbents.—The most available, as well as the most economical, of the second class of disinfectants is charcoal.

This may be used very efficiently in covering over the surface of the contents of a privy-sink or cesspool; or it may be very beneficially mixed with lime unslaked —in the proportions of one of charcoal to two of lime. These two agents more completely cover the whole ground in the matter of general disinfectants than any of the others.

In disinfecting old dwellings, as has already appeared in the instructions of the Health Board, the smoke of a wood fire is an ever-ready expedient. Dry lime sprinkled on moist or oleaginous surfaces has also repaid the experimenter with the most beneficial results.

Of the *antiseptics*, the metallic salts are the most useful as deodorants. Among these may be mentioned—

1. Solution of nitrate of lead (℥ j. salt to ℥ j. water).
2. Solution of the chloride of zinc.
3. Solution of the sulphate of copper.
4. The salts of iron—the protosulphate and the protochloride. The salts of iron are very prompt in controlling ammoniacal, sulphuretted, and other noxious effluvia; hence very useful and convenient in deodorizing evacuations by vomiting or by stool.
5. Permanganate of potassa—one of the most useful and efficient of the class, has but one drawback, to wit, expensiveness.

It is particularly efficacious in topical applications, in dressing wounds, old ulcers, and the like. To purify infected apartments, cloths saturated in a strong solution of the permanganate may be suspended.

Another very useful purpose for which a solution of the permanganate may be employed, is the purification of water. Drop small quantities into the water until the beautiful tinge of the permanganate begins to appear. Shake well, and deodorization immediately takes place, and water which otherwise would be very offensive from decaying animal or vegetable matters, may become wholesome, tasteless, and drinkable, and the effect of the necessary amount of permanganate is to render the water tonic in its effects, and not in the least objectionable.

5. Carbolates.—Creosote, carbolic acid, and coal-tar are each very effective as antiseptics, and not only arrest the putrefactive process, but as long as it is in the pabulum subject to change, it prevents the recurrence of putrefaction. But owing to the fact that they are easily decomposed through chemical reactions, their effects are somewhat limited.

Their offensive smell renders them objectionable to some extent in dwellings, but they are very valuable in disinfecting sewers, drains, privies, stables, and the like. Coal-tar may be used for chamber vessels by mixing equal parts of coal-tar, alcohol, and soft-soap—a small quantity only is required.

Heat.—For the purpose of disinfecting clothing, merchandise, or fomites of any kind, a temperature of 250° may be employed with entire success, without any danger of injuring the color or the value of the finest textures. Rooms or ovens may thus be heated for the effectual disinfection of goods, clothing, etc., which have arrived at quarantine from an infected port.

But assuming as correct the theory that the so-called zymotic diseases owe their origin to a catalytic change in the blood set up by the introduction of an extraneous substance, the question most pertinent that now presents itself is—after the blood poison has entered the circulation, what are the *indications for treatment?*

1st. Neutralization of the poison; and 2d. Elimination.

Under the general expression neutralization, it is proper to mention, are included the different processes which may occur to put a period to the influence of the poison—whether it be by combining with the nervous element, and forming a compound on which the poison is incapable of producing an effect—as is supposed is the case in the result of giving arsenic and quinine in ague, or by the use of agents which will render the blood, or that part which is affected by the poison, unfermentable; or by the direct effect of oxidation by union of the poison with the remedy.

In the treatment of some forms of the contagious diseases, such as syphilis, gonorrhœa, puerperal fever, and erysipelas, the disease undoubtedly may be aborted by

burning out the virus previous to its extending from a local to a constitutional disease. In the case of puerperal fever or erysipelas, the nidus is so subtle that the initial point for abortive treatment must be carried back a step further, and the physician or nurse should thoroughly wash his hands, instruments, etc., in a solution of permanganate of potassa, creosote water, or some efficacious disinfectant.

In case of infectious diseases, if there be a class of remedies by oxidizing the poison or rendering unfermentable its pabulum, their general application would indeed be a forward step.

That there are such a class of remedies has been claimed by Dr. Giovanni Polli, in his often-quoted communications to the Royal Institute of Lombardy, at Milan.

Results so far seem to favor his theory, since *pyœmia septicœmia*, and all the class of fevers with putridity and purulent absorption, such as hospital fever, and puerperal fever, anatomical inoculation, etc., have been treated by the alkaline sulphites with advantage.

Miasmatic fevers are treated with the sulphite of magnesia with great efficacy.

Numerous reports are given of their value in the *exanthemata* and *typhus fever*.

The general results reported are to the effect that they mitigate the intensity of the febrile exanthem, render the confluent and malignant forms more benignant, shorten the course of the milder forms, and in all cases accelerate convalescence.

Dr. Polli does not state that they will prove available in curing cholera and plague, but thinks they will prove highly useful as prophylactics.

The plan of Dr. Polli has to recommend it that it is rational, and as the sulphites are innoxious in their effects, it is to be hoped that the profession in this country will give it a thorough trial.

It appears that in order to get the curative effect of these medicines, it is best to saturate the system. For rapid sa uration the sulphite is better than the hyposulphite.

Of the sulphite of soda, four or five drachms a day, dissolved in water, is the minimum dose. But for the prophylactic effect the hyposulphite is preferable.

Elimination.—In taking general ground as to whether or not the eliminative treatment is to be adopted in the treatment of zymotic disease, it cannot but be granted that the indication exists, if we accept the fact of the blood containing an extraneous poison.

It must certainly be conceded that throughout the whole class of zymotics there is running through each particular disease a similarity that links the whole together, exclusive of the similarity of the causes.

There is a prodromic, incubative period common to all, during which there comes on constitutional disturbance, which is fever. Then, after the acme of the disease has been reached, "when the leaven has leavened the whole lump," there is seemingly an effort of nature to cast out the *materies morbi* which has caused the disturbance. The increased activity in the exanthemata is exhibited in the skin; in plague in the glands. In typhoid fever the glands of the intestines are chiefly implicated, whilst in cholera and dysentery congestion of the abdominal viscera is present.

But because there is an indication that nature points towards the open door of any particular emunctory, it is not to say that all the treatment should tend to stimulate activity in that direction. On the contrary, in some instances it is eminently proper to make a diversion in favor of an already overburdened organ.

The paper concluded with remarks upon the therapeutics of cholera, in which it was maintained that opiates, alteratives, and astringents were really eliminative agents, which gradually directed the poison to the different emunctories.

The Association then adjourned.

Progress of Medical Science.

THE SURGERY OF THE ARTERIES has been signally stamped by the progressive conservatism of the day—thus far testimony inclines against the knife. Of 17 published cases of aneurisms and wounds of arteries, 8 were treated by ligature, of whom 6 recovered and 2 died; 9 were treated by compression direct or digital, and indirect or by tourniquet—*all* recovered.—*Med. Record* (*May* 1.); *Lancet*, i. 1; i. 9.; *Med. Times & Gazette, Mch.* 30, *p.* 335; *Am. Journal Med. Sciences*, vci., *pp.* 402–500; *Ann. Univers*, cxcix, *p.* 351. *Brit. Med. Journal, Mch.* 16; *Lancet* i. 4; *Gaz. des Hôp., Nos.* 25, 36; *Petersburg Med. Ztesch., vol.* xii, *No.* 213, *p.* 137.

THE THERAPEUTICAL ADVANTAGE OF POSITION IN THE TREATMENT OF SHOCK.—The following case is presented in the *Chicago Medical Journal*, by Hiram Wanzer, M.D.: March 16th, J. T., æt. 9 years, had fallen through a hatchway, alighting upon his head, and was taken home in a state of profound insensibility. There was scarcely any pulse when I arrived, and the heart's action was nearly suspended; there was general pallor of the countenance and coldness of the extremities, every symptom indicating early dissolution. I immediately raised the body and legs to an angle of 45°, and in less than 15 minutes, quite a full pulse returned at the wrist; the action of the heart was stronger, and the glow returned to the cheeks, showing that the capillary circulation was being established. He was now placed in the recumbent posture to remove his clothing and examine his body for injuries, and in a moment the blood forsook the wrist, and the heart's action was again more imperceptible. I thought he was gone. I placed him instantly in the former position, and in less than five minutes the pulse returned, and the heart began to beat with renewed vigor, and the brain responded to its acccustomed stimuli. The *rationale* of the treatment—the blood returned to the capillaries, and the machinery of life, temporarily suspended, was again set in motion. He remained in this position thirty minutes longer, when he was placed in the recumbent posture. Cold applications were applied to the head, and hot epithems to the feet, and an enema of whiskey, ʒ ss. with gum camphor gr. v. was given. This measure assisted in completing the reaction. His convalescence was exceedingly rapid, but he was speechless 24 hours.

HYPODERMIC INJECTIONS IN PUERPERAL CONVULSIONS.—Dr. V. H. Taliaferro in the *Atlanta Medical and Surgical Journal*, speaks in praise of hypodermic injections of morphia in a case of puerperal convulsions occurring in his practice. The convulsions had lasted several hours, and the head was well impacted in the inferior strait. On his arrival at the bedside, chloroform was immediately given, but did not control the convulsions until after she had been bled from the arm. Nearly three hours elapsed before the child was delivered with forceps. The patient was at this time in an "alarming condition from profound coma and great prostration." A grain of morphia was now administered by hypodermic injection, and the patient left until the following evening, when the operation was repeated. On the following morning the patient was but little improved. The injections were repeated as on the previous days,

morning and evening. On the third afternoon the morphia was discontinued, and the patient aroused, sat up in bed, and spoke to her attendants. From this time the recovery was rapid. Dr. Taliaferro thinks the "recovery of the woman mainly due to the hypodermic administration of the morphia, whereby a sufficient narcotism was induced immediately following delivery, and kept up until reaction had quietly and firmly established itself, avoiding thereby the violent reaction which would in all reasonable probability have ensued, and resulted in the most active inflammation, establishing itself, most likely, in the peritoneum, the uterus, or both."

Imperforate Anus in the Hog.—J. M. Johnson, M.D., relates, on the authority of Capt. McDaniel of Atlanta, Ga., a very curious circumstance, which can be verified by a number of witnesses. Mr. John E. Gadsey, of Franklin, Tenn., raised a male hog to be eighteen months old with imperforate anus. The animal was always fat, and in every particular, except the one mentioned, properly developed. After retaining his food for a certain length of time, feeding as other hogs, vomiting would ensue, and then, with an appetite as keen as ever, he would go to his meals again. He was killed at the age of eighteen months, was thoroughly fat, and to all appearances in perfect health.—*Atlanta Medical and Surgical Journal.*

Experience in the Treatment of Cholera.—In a communication to the *Cincinnati Lancet and Observer*, Dr. S. S. Todd, of Kansas City, advocates the use of cantharides in connection with dilute sulphuric acid. He says: "From a desire to have the plan thoroughly tested, I give my practice in a limited number of cases with the results:

"First, ten grains of mass hydrarg. and a large plaster of cer. cantharides, applied early over the stomach and bowels; to be removed before vesication if the symptoms abate. It is designed that the active principle of the fly shall be absorbed. Second, the following mixture: ℞. Tr. cantharid. ʒij., acid. sulph. dilut., syr. tolutani, *aa* ℥j., tr. opii ʒij. M. For an adult, two teaspoonfuls of the mixture in a wine-glassful of water every half hour or hour. If rejected by the stomach, *repeat at once* until retained. When the more alarming symptoms abate, administer more sparingly. This is intended for use prior to collapse, and as soon as diarrhœa or vomiting first occurs, and immediately following the mercurial. For collapse, the same, except that the tincture of opium is omitted, and the dose increased to three teaspoonfuls. One of the most remarkable and invariable effects is the immediate cessation of cramps, if they have been present. The pulse, too, is increased in fulness, and the heat of the body augmented. This is often seen temporarily in those who are beyond recovery. How far these results are due to the sulphuric acid, I am unable to say, as I have not used the cantharides except in conjunction with the remedies named. No alcoholic stimulant is allowed, and cold water is given by the teaspoon only. The extremities are kept warm with a dry heat. They should be kept well covered and no rubbing allowed. The patient should take the bed on the appearance of the first symptoms, and the most absolute quiet of the patient and surroundings should be preserved. If the case is dangerous, he should not even be allowed to turn over in bed, and should be prevented from getting up to have his evacuations, and urged to restrain them as long as possible. The first dose of the medicine is usually rejected, but if it is repeated immediately, it will be retained. Strangury is rare, and if produced, is easily removed by a dose of morphia. From the 13th of August, to the 1st of November, 1866, I had twenty-three cases under my exclusive care, and all of them were subjected to the foregoing treatment, with slight variations. In no case was the blister omitted, and all had the tincture of cantharides and dilute sulphuric acid in very nearly the proportions given. Of these 23 cases, 16 recovered and 7 died. Of the cases of recovery, 6 were of mild character, attended with vomiting or purging, or both; 7 were of a severer type, and partially collapsed, while 3 were completely collapsed. In none of the cases was there consecutive fever. Most of the cases were seen and treated early. In one case only had the disease existed over ten or twelve hours, and in this case complete collapse came on shortly after my first visit. This patient was able to leave his bed in five or six days. I do not hesitate to express the opinion that a majority of the fatal cases might have been saved by the medication described, had they been timely treated. Comparing this treatment with that I saw adopted in 1849–50, when calomel and opium were the remedies chiefly relied on, I am impressed with the belief that we are rapidly tending to the point when cholera shall be shorn of half its terrors."

Dr. Todd also calls attention to the use and probable value of the dilute sulphuric acid as a prophylactic in epidemic cholera. A fluid-drachm in a wine-glassful of water, before breakfast and before retiring at night, is sufficient. He and a large number of others have used it with complete satisfaction. Many of the parties were exposed for several consecutive days as nurses, and none of them took the disease.

Obstruction of the Bowels from Accumulation of Cotton Yarn.—Dr. C. T. Gardner reported (*Boston Med. and Surg. Jour.*) to the Providence Medical Association, a case of the above. The patient was a female, aged 26 years, a weaver by occupation. When Dr. Gardner first saw the patient, she had symptoms of enteritis, pains and tenderness of the abdomen, accompanied by vomiting. Bowels constipated, nights sleepless. In the emesis, he discovered a small quantity of cotton yarn. On inquiry, he learned that the patient, during the past six months, had been in the habit of chewing cotton yarn and swallowing it. To relieve the pain, he injected sulphate of morphia, hypodermically; this was followed by castor-oil, producing copious evacuations of the bowels, and revealing the cause of her illness, in the shape of some half-pound of cotton yarn. Dr. G. exhibited a portion of the yarn. The health of the patient previous to this illness had been good, the catamenia being regular; and she had no morbid propensities in relation to eating.

Puncture of Bladder per Rectum.—Recovery.—Dr. B. F. Hart, of Marietta, Ohio, in a private letter to a friend, reports a case of successful puncturing of a distended bladder, after all the ordinary means had been resorted to. The operation was performed per rectum by means of a trocar and canula. The cause of distension was an impassable stricture.

Ligature of Subclavian Artery.—The left subclavian artery was ligated, November 14, 1866, by Dr. T. G. Morton, Philadelphia, for spontaneous aneurism of the axillary. The patient recovered and was discharged on the 115th day, after having survived an unusual number of secondary complications, including twelve hæmorrhages from collateral vessels, which brought him three times to death's door, and, at last, sphacelation of nearly the whole arm. The ligature of the subclavian was placed upon its second portion, the wound healed perfectly, and the ligature came away on the eighteenth day.—*Am. Journal of Med. Sciences.*

Bromide of Potassium in Affections of the Testes.—Dr. Bedford Brown, of Washington, D. C., has, for ten years past, found the bromide of potassium very useful in diseases of the entire genito-urinary system, especially in affections of the ovary and testis. The earliest effect which he has noticed is a positive diminution of pain, and relief to annoying phenomena attendant. He thinks that this sedative power is displayed even in cases in which no more decidedly curative effect is produced. For the state thus induced he suggests the term *brominism.—Am. Jour. of Med. Sciences.*

Solvents for Cholesterine, Etc.—In an interesting and important article in the last number of the *American Journal of the Medical Sciences*, Dr. T. H. Buckler, of Baltimore, relates his experience with chloroform and succinate of the peroxide of iron as solvents for cholesterine and cholesteric fat; he has invariably found them successful. The chloroform is used in teaspoonful doses every hour during the existence of acute pain produced by the impaction of calculi in the duct of the gall bladder, and after each meal, when the urgent symptoms have subsided. But although, both on account of its solvent and its anæsthetic powers, chloroform was found by far the best remedy for the acute symptoms, it had no efficacy to prevent the formation of other stones. Considering that the difficulty of dissolving cholesterine depends upon the small amount of oxygen which it contains, it was thought that substances containing oxygen in large proportion would be most likely successfully to combat the cholesteric tendency. With this in view, the peroxide of iron and succinic acid were selected, and from them Dr. Stewart, the chemist, of Baltimore, prepared the hydrated succinate of the peroxide of iron. This substance, when taken in about 15 grain doses after each meal for more than six months, had the effect of preventing the accumulation of biliary calculi. It is also stated that this salt may be used with advantage by persons having a tendency to obesity, or where there seems a probability that fatty degeneration is invading the heart or other organs. Dr. Buckler considers it important that this succinate should be prepared in the hydrous state, and kept constantly in a water bath, as, if dried, it does not dissolve in water.

Operation for Relief of Artificial Anus.—Dr. Kinlock, of South Carolina, reports in the *American Journal of Medical Sciences* a case of artificial anus, from gunshot wound, in which *seven months* after the reception of the injury, during which time the function of the lower portion of intestine had been suspended, he succeeded in uniting the upper and lower portions, and converting the artificial anus into fæcal fistula, by which means the patient was rescued from approaching death by starvation. The condition of the parts was such that it was necessary to lay open the peritoneal cavity and break up the adhesions already formed. The results were not all that had been expected, but were sufficiently beneficent to serve as an argument against the practice of abandoning intestinal lesions to nature. Three years after the operation the patient weighed over 200 pounds, and could ride half a day, or walk a mile without resting.

Index of Physical Endurance.—Dr. Ruschenberger, of the Navy, concludes that the length of the cerebro-spinal axis, measured from the perineum to the vertex, affords a better index of physical efficiency than the total height of a man. Adverting to a paper in which Dr. B. A. Gould states that the "tall men did not wear as well as the shorter," he remarks: "Observation has led me to conjecture that, as a rule, men of average height, made up of a long trunk and comparatively short lower extremities, possess greater power to endure with impunity great labor and exposure to vicissitudes of all kinds than men who have comparatively long lower limbs and short trunks. A long and otherwise fully developed trunk affords more space for the accommodation of organs essential to life than one of smaller dimensions. The size of the contained organs is proportionate to the capacity of the cavities provided for them; and it may be assumed that all things being equal, the size of an organ is a measure of its power.—*Am. Journal of Med. Sciences.*

Cerebro-Spinal Meningitis.—In an analysis of one hundred and sixty-one cases of cerebro-spinal meningitis, which occurred at the Philadelphia Hospital during the winter of 1866 and 1867, Dr. Githens makes the following statements:

The patients ranged from eight to sixty-eight years of age, and with few exceptions were intemperate and irregular in their habits; they lived in filthy neighborhoods, in crowded tenements, and frequently in underground apartments. The disease showed no signs of contagiousness, the cases being confined to no particular part of the house; two cases rarely came successively from the same ward. About a week of prodromata generally preceded the attack; there were muscular pains, general soreness, tenderness of the surface, so that a touch became painful; nausea and bilious vomiting, but little or no disturbance of the bowels. The eruption, which was one of the symptoms generally ushering in the real onset of disease, was not at all uniform in character, while thirty-seven out of ninety-eight cases had no eruption at all. The peculiar expression of countenance, the depressed corners of the mouth, the wild, staring, watchful gaze of protruded eyes, and the congested conjunctiva, were characteristic. Thirst as insatiable as in cholera wasmarked and persistent. The temperature was lower than is recorded of any other typhoid disease, ranging from 100° to 105°. The duration, including prodromata, was in many cases from twenty to thirty days. Death occurred in a little over 26 per cent. of the cases treated. Carbuncles and boils were frequent sequelæ; deafness, more or less marked, resulted in sixteen cases.—*Am. Journal of Med. Sciences.*

Elephantiasis Græcorum; both Common Carotids Tied.—Dr. J. M. Carnochan reports to the *Am. Journal of Med. Sciences* a case of the above disease, which had invaded the skin and subjacent tissues of the face and neck, spreading from a small pimple below the right corner of the mouth, until, at the end of fourteen years, the parts presented the appearances characteristic of leontiasis; sight, hearing, and smell were gone, from obstruction, and taste and sensation were blunted. In the early course of the malady excision of the individual tubercles as they appeared, and later, constitutional treatment had been tried without essential benefit. In November, 1858, the right common carotid was ligated, and the operation caused so great a diminution in the size of the morbid growth that sight and hearing were restored. At the end of six months, the disease appearing to be stationary, the left common trunk was tied. This caused a still further improvement, which continued until the fall of 1860, when the curative process was apparently passive. During the next six years various secondary operations were performed for the removal of nodular masses which had either appeared since the operations, or not shrunken equally with the surrounding parts, until, in December of 1866, it could be noted that there was no disposition in the disease to extend, but, on the contrary, to further diminish; the senses were perfect, the operation of the brain unimpaired, the general health excellent, the spirits good, and the patient a useful member of her household.

MEDICAL CLIQUISM.

THE strong tendency to aggregation which is manifested by similar particles is a prime fact among the phenomena of the material universe. Star-dust will not lie in nebulous masses, but ever resolves itself into separate suns, each one, doubtless, with its attendant planets circling through infinite space. To the same law the rock-ribbed earth is found obedient, as the orderly stratification of its crust bears witness; and when to inanimate matter the higher principle of life is introduced, the uniform activity of corresponding forces becomes still more apparent. The terse old saw concerning birds of similar p'umage has lost none of its truth. With the affinities which group individuals of the human race, all are familiar. Regarding the custom of the angelic hosts it may not be prudent to inquire, but there is high authority for the belief that even "devil with devil damn'd firm concord holds."

With such an array of facts from the order of nature ever before their attentive eyes, it might be supposed that the members of the medical profession would constitute the most harmonious brotherhood imaginable. Animated by the spirit which community of pursuits should engender, the noble army of doctors might not unreasonably be expected to present the charming spectacle of a body of philanthropists, cordially coöperating for the good of humanity and of—each other. Strict regard for scientific accuracy, however, compels us to conclude that we are yet far from realizing so happy a picture. Close inspection shows the mass of physicians divided into little societies, clubs, or cliques. The members of these fraternities are held together either by sentiments of mutual admiration, by a show of scientific zeal, or with shame be it said, by disappointment and jealousy. Men of congenial temper are instinctively drawn into contact. Some one, of perhaps more than average ability, forms the nucleolus of the happy band. Mirror-like he reflects the compliments of his friends, who in turn are too polished to absorb such comfortable radiations. All is light and warmth in these pleasant circles. It is the old story of the oak and the ivy—fair to the eye, and without reproach till perchance the venerable trunk has surrendered life and substance, when the whole growth, late so leafy and graceful, falls suddenly to earth, a most pitiable ruin. All this, however, is harmless enough. The tie of friendship is as sacred and as worthy of honor when it unites the members of our profession as when it draws together any other harmonious souls. It is only when mutual esteem degenerates into mutual flattery, begetting exclusiveness and contempt for outsiders, that such association degenerates into cliquery.

Upon the solid foundations of the medical schools, are usually based cliques of a scientific sort. Here are gathered the high-priests of the profession, so many at least as can gain admission to the ranks of the faculties, and around them cluster a swarm of neophytes ready alike to fill the air with a hum of applause at the dicta of their chiefs, or to fly in the faces of all who would doubt the prowess of their champions. Very worthy and very useful bodies are these, so long as they are content to "improve each shining hour;" but when rivalry or opposition stirs the hive, alas! for defenceless humanity!

It is in this connection that we feel constrained to remark upon certain practices which are in vogue among the members of these corporations. The rivalry of the schools excites their officers to every possible effort for the attraction of students, not merely by the quality of the instruction imparted, but by the hope of assistance and advancement after graduation. For these hopes the younger men are expected to lend their backs as stepping stones for the progress of their master, whose personal ambition is after all the main-spring which sets in motion so many wheels of selfishness. With all this, however, fault could not be found, were not the most unwarrantable methods of advancement, copied from the lowest forms of political trickery, too often adopted by men whose position and renown should place them above all that is dishonorable. It is impossible to convict these offenders; for such is the organization of the cliques in which they move, that upon no individual member can be charged the responsibility for any given act.

Another flagrant abuse of the principle of association is shown by the fact that in consequence of these cliques it has become well-nigh impossible for any one outside of the number of their favorites to obtain a position in our hospitals and colleges. Scientific attainments weigh but lightly against the influence of a well-organized club. When a vacancy occurs on the staff of a hospital or in the faculty of a college, it does not seem so much a question of intellectual fitness which first arises concerning the candidate, as the nature of his connections and the degree of his availability. Who are his patrons? What will he do for me? These are the questions which occupy too much the minds of those who have a voice in the matter. In this way our college faculties and hospital boards become the most exclusive

bodies, of whose members too many will stick at nothing for the gratification of their own selfishness. This is one of the evils which recoil upon the malefactor, for no one can be at the same time a college professor, a physician or surgeon to three or four hospitals, and the master of a large practice, without losing ground as a man of science. This overreaching ambition renders the lives of some of our ablest men almost useless to the profession, and hinders the accomplishment of anything which may serve in future as a monument to their memory. Could a tithe of the time which these gentlemen now spend in racing from one operating theatre to another be occupied with careful study and collation of their cases, how much more enduring would be their own reputation—how much more instructive the medical literature of their day!

Basest of all the cliques are those which have for their object money. Science, honor, the esteem of their fellows, all go for naught with men who for gold or for the hope of gold are willing to enter the organized cliques into which quackery subdivides. Lamentable, indeed, is the spectacle presented by the young man who at the outset of his professional career, destitute of principle, and only ambitious for pecuniary success, stands balancing with all his feelers in motion, seeking admission to some little association which shall bear him easily on to fortune. To become the satellite of some great man, or a noisy member of a mutual admiration club, or the appendage of even a political party which may have favors to bestow, these are his first objects of desire. Failing here, the unscrupulous fortune-hunter consents to discuss homœopathy, eclecticism, whatever disreputable thing may promise most. Surely and rapidly downward tends the course of the adventurer, no matter how fair the mask with which he seeks to captivate the eyes of the world. When shall the noble title of physician be no more defiled by these carrion-crows of the profession?

Do these facts seem to contradict the law of nature? On the contrary, they exhibit exact conformity with that law. Like seeks like, and congeniality will govern the association of the best of men. It is only the abuse of what is in itself good that gives occasion to the complaints which are rife. Physicians are but men; and while they continue to be animated by the motives which influence the mass of mankind, it is useless to expect greater unanimity. Only when the spirit of the golden rule shall become alike the guide of the philosopher and the peasant; when the lion shall lie down with the lamb, and doctors cease to disagree, will cliques and all their attendant evils be known no more.

During the past fortnight, Mr. T. Spencer Wells, of London, has paid a visit to this country, and it should be a cause for congratulation among American physicians, that he carries with him such a high opinion of our professional character, and our institutions. During his sojourn, at first in Canada, and afterwards in Philadelphia, New York, and Boston, every professional courtesy has been extended to him, to which his enviable reputation as one of the most celebrated operators of the age entitle him. The letter from our correspondent in Philadelphia gives us a graphic account of his doings in that city, and his reception there. It is needless to say that our own city was not behindhand in tendering professional courtesies to the great ovariotomist. While here, he was the guest of Prof. B. Fordyce Barker, who kindly invited his professional brethren to meet Mr. Wells at the Mott Memorial Library, and the large number in attendance on that evening must have shown the distinguished foreigner that his services in the cause of science had been duly and appreciatingly recognized. With a taste that is in every respect to be commended, the gathering was a purely social one, and everything was done to make the evening pass pleasantly and profitably, not omitting the elegant supper provided for the occasion. The selection of the building was a good one, and was singularly appropriate as honoring the name of one of our illustrious dead, by the presence in the Memorial rooms of one who has written the most touching and chaste obituary of Dr. Mott which has ever emanated from the transatlantic press. It is perhaps needless to call to the mind of many of our readers that the memoir referred to was the one penned for the columns of the *Medical Times & Gazette*, of London. The occasion was a rare one, and was seemingly as pleasant to the guest as to the rest of the company.

The day following, in company with Dr. Emmet, he visited the new Woman's Hospital, just opened, and the New York Hospital in company with Dr. C. M. Allin, one of the visiting surgeons. By special invitation the succeeding day, he offered some remarks upon the subject of ovariotomy, to a large and appreciative audience, who were at the same time delighted with his easy and elegant delivery, and edified by his practical and common-sense observations. The substance of his remarks will be found in the letter from Philadelphia. Starting, after this short stay, for Boston, he remained in that city for a few days, and departed last Wednesday for his home.

During his lecture at Bellevue, in speaking of the character of our physicians, and of the means which they had at their command for the study of disease, he made the remark that British physicians should now think as much of coming to this country, and making themselves acquainted with what was being done here, as we formerly did of taking a trip to Great Britain. This, coming from such a source, is full of significance, and should encourage us to profit still more from the means so abundantly placed before us. He can be assured, in turn, that he carries with him the esteem and admiration of his American cousins. It is a pleasing task to record such interchange of courtesies, and we hope to be able soon to have another occasion to perform a similar one.

Reviews.

THE PRINCIPLES AND PRACTICE OF DISINFECTION. By ROBERTS BARTHOLOW, M.D. Cincinnati, 1867. 12mo, pp. 111.

THIS is a very useful manual on the subject of which it treats, and is in a form very convenient for use. The author, in his first chapter, speaks of the substances on which disinfectants are intended to act; which he divides into two classes: 1. Those developed in the process of putrefactive decomposition of animal and vegetable matter; and 2. That peculiar organic matter to which we apply the terms virus, *materies morbi*, morbific matter, diseased germinal matter, etc. It is assumed with great probability, contrary to the theory of Liebig, that *materies morbi* is *living matter*. If so, the *zymotic* theory must be abandoned, together with the nomenclature founded on the doctrine of a *ferment*. Discovery and science seem rapidly tending in this direction. We never were fully persuaded of the truth of Liebig's theory of fermentation in living bodies. Our townsman, Prof. Paine, has well-nigh exploded all this. Prof. Beale now comes in to declare the theory "not only unreasonable in itself, but as obstructing the progress of knowledge." What then? Are we prepared to embrace a theory of disease based entirely on microscopic researches? Shall we believe Dr. Beale and others when they assure us that the power of growth and the production of tissue depend upon minute masses of "germinal matter," and that there is no distinction, chemical, physical, or microscopical, between the normal germinal matter employed in building up tissue, and the abnormal or diseased germinal matter which excites the phenomena of disease? We are not about to dispute this point; if a microscopist claims to see what no one else has ever seen, or not to see differences acknowledged by all others to exist, we think, instead of taking his statements as truth, it is better to wait for further observations and developments. We are in no hurry on these theoretic points, we can afford to wait; and we think it by far the safer course to adopt. It is becoming quite too common to overlook the vital endowments, and vital properties. On Dr. Beale's theory we don't see why all diseases should not be communicable, for, if the degraded germinal matter, which is contained in discharges from the lungs, skin, and intestinal canal, fall into suitable soil, they will grow and multiply, and thus propagate these diseases, and as the atmosphere is said to be filled with all manner of diseases, the germs of *vibrio*, *cacteriæ*, and *monads* of the animal kingdom, and spores of *fungi*, *mycoderms*, and *mucedines* of the vegetable kingdom, *pus* cells in hospitals, and *cholera* cells wherever this disease prevails, the theory of disinfection becomes simplified, so that, instead of confining our attention to destroying noxious gases, and the volatile products of putrefactive decomposition, we must especially seek to attack and destroy these *cells*, the *virus* of disease, the *materies morbi*. We must direct our attention to diseased *germinal matter*. *Foul odors* are nothing, except as they lower the vital forces, the power of resisting and throwing off disease; in other words, preventing the action of this morbid cellular growth—disease-producing matter. Where must our disinfectants be applied in order to be efficient? Evidently, where the diseased matter is. In cholera, to the choleraic discharges; in small-pox, scarlatina, etc., to the air in which the germinal cellular matter floats.

Chapter II. treats of the "*Mode of Action of Disinfectants*." In this we discover nothing new. The author first describes the agents that chemically destroy the noxious compound. Second, Those that arrest chemical change, antiseptics. Third, Agents that physically restrain the noxious compound. Under the first class he ranks *heat*, *ozone*, *chlorine*, *bromine*, *iodine*, *nitrous acid*, *sulphurous acid*, and *the chlorides* and *sulphates of mineral bases*. Of these heat is considered the most powerful, and may be assigned to each of the three classes.

Chapter III. treats of the "*Application of Disinfectants*," under the following heads, viz.: "Disinfection of air," "disinfection of solids and liquids," "of water," "of the discharges of the sick," "of cesspools," "of clothing, bedding, etc.," "public disinfection," "purchase of disinfectants, etc." To these is added a notice of recent papers on disinfectants. Altogether the work is creditable to the well-known talents and industry of the author, and we would strongly recommend it as the best manual on the subject yet issued from the press.

Correspondence.

MEDICAL MATTERS IN PARIS.

(FROM OUR OWN CORRESPONDENT.)

PARIS, August 19, 1867.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—The School of Medicine held its annual closing ceremonies on the 14th. M. Béhier pronounced an eloquent eulogy upon Rostan. On the 17th the amphitheatre of the Ecole was again filled to celebrate the opening of the International Medical Congress, where seven hundred physicians from all parts of the world, representing nearly all the celebrated physicians living, had gathered together.

THE INTERNATIONAL MEDICAL CONGRESS.

The hemicircle was draped with the flags of all nations. The eagle of Prussia floated in the midst of the colors of France, and the Turkish crescent fraternised with the banner of England. M. Bouillaud presided, supported on the right by M. Gavarret, on the left by M. Tardieu, and pronounced an eloquent address, whose feeling was responded to by every member of the great assembly. When the illustrious professor said, "I cannot contemplate this scene without being profoundly moved; I feel my feeble powers fail to express the just sentiment of the occasion," all the audience replied by bravos the most sympathetic; and when the orator concluded, "Let us rise to salute these entwined flags, and then unite our hands as they are united, in sign of complete and cordial fraternization," the enthusiasm was at its height, and the amphitheatre resounded with a thunder of applause.

But alas! having been at its height, it was all the more liable to fall. The day was very hot, and the old amphitheatre was constructed for other purposes than those of ventilation. The question of the day was tuberculization; and after the reading of the first memoir, the audience began to reflect, to calculate that many more were to follow, that they were "in" for three or four hours at least. People grew restless and anxious. Presently every one was electrified with a voice, whose timbre, entirely exotic, pierced right through the decorum of the assembly.

"M. President, is it permitted to ask a question?"

"Certainly; speak."

"I am a stranger; I am a physician from Holland,

and as a Hollander I have been invited to assist at the International Congress, but I find I have made some mistake; for in my opinion this is no congress, but a class, a school-room, where some doctors have come together to admire each other, and hold themselves up for admiration."

Literally, that is what the honest Dutchman said. He spoke with all the traditional phlegm of his race; he scanned each word, and the ironical syllables fell into the midst of the "band of brothers" like so many bomb-shells. Of course there was confusion, and calls to order; then, finally, the reading of the papers on tuberculization was resumed.

The other questions that will occupy the Congress are as follows:

Second Session.—Continuation of the discussion on tuberculosis. Discussion on the influence of climates, races, and different social conditions upon menstruation in diverse countries.

Third Session.—On the constitutional accidents which occasion death after surgical operations.

Fourth Session.—Is it possible to propose to different governments efficacious measures to restrain the propagation of venereal diseases?

Fifth Session.—On the acclimatation of the races of Europe in warm countries.

Sixth Session.—On the influence of alimentation upon the production of certain diseases in different countries. (The memoirs announced upon this question all relate to pellagra.)

And in the same séance will be developed some considerations upon entozoa.

This programme promises well, some of the topics being of extreme interest and importance, and only capable of being studied in the light of the experience of physicians of many nationalities. All the medical world that is not at the congress has gone into the country, whither we will follow them, and collect some gleanings from the rich harvest of the provincial societies, which in intelligence and learning are not inferior to those of Paris.

THE CONTAGION OF CHOLERA.

The Imperial Society of Medicine at Lyons, in the séance of the 15th of July, listened to a dissertation by M. Rodet, upon the capital question of the contagion of the cholera. M. Rodet, who occupies a middle ground between the non-contagionists and the contagionists, commenced by citing a certain number of facts that had been adduced by each party in proof of its theory. On the side of the first, four. In 1835, the vessel Ville de Marseille was stationed two or three miles from Toulon, where the cholera was then raging, and the crew had frequent intercourse with the infected city, yet not a person took the disease. In 1831, among a hundred nurses and attendants upon cholera patients in the hospital at Cairo, not a single person took the cholera; eighty nurses in the hospital of Monsourah have enjoyed the same immunity; and among sixty at the hospital at Damiette, only one took the cholera. Again, at the Hospital of the Dey at Algiers, the immunity of the persons attached to the cholera wards was so great in 1865, that one might have supposed them to be asylums of refuge. Finally, in the Military Hospital of Constantinople, 1,488 cholera patients were received from the 27th of January, 1855, to the 31st January, 1856, of whom 658 died. Their clothes and linen were washed by the hospital attendants; the privies exhaled from time to time fetid emanations, which spread throughout the hospital, and even beyond its precincts; yet in spite of so many conditions favorable to contagion, the disease was not communicated to any other patient, or to any of the persons attached to the wards.

It is noticeable, however, in connection with the first case cited, at Toulon, that although the crew of the Ville de Marseille was so remarkably spared, twelve physicians succumbed to the epidemic. In 1865, there perished in the same city six physicians, two apothecaries, ten nurses at the marine, and five at the military hospital, in all twenty-three persons connected with the care of the cholera patients.

In these cases, however, the non-contagionists may still urge, that the victims were at the same time exposed to epidemic influence, so that it is impossible to tell what share contagion had in the infliction of the disease. This argument does not hold in regard to seven other cases quoted by M. Rodet, occurring during various epidemics, and one related in detail by M. Petiteau, that he observed last September. In all these cases the infection seemed to be directly transmitted by persons going from an infected to a healthy locality, was first communicated to persons with whom they came directly into contact, and thence from individual to individual, over a certain radius, after which the morbid influence seemed to be extinguished. In only one case was a wide-spread epidemic excited. In five of these eight cases the disease was imported by people who had visited the infected locality, merely during a few hours or days, and were attacked shortly after their return home, communicating the disease to those who nursed them. In M. Petiteau's case the attendants on the patient escaped, but after his death a drunken comrade, who persisted in passing all night by his corpse, embracing it, and committing a thousand extravagances, was speedily smitten. Twelve cases followed this infection, of which six died. In the cases cited by Rodet, for the first, only the son and husband of the original patient died, while she recovered, and the disease went no further. In the second instance, only the mother of the patient was carried off, while he recovered. In the third, fourteen persons perished out of a population of 130 inhabitants. In the fourth, there were thirty-one deaths in thirty-four days. The other three instances of infection mentioned by Rodet were occasioned by the flight of persons from places where they had lived, for some time during the prevalence of the epidemic, into healthy localities. In the first case, a general epidemic was lighted up. In the second, all the members of a family living in different houses were successively attacked. In the third, twenty-seven persons were attacked, of whom twelve succumbed.

M. Rodet, although attaching full importance to these facts, as proof of the communicability of cholera by direct contagion, is careful to point out that such influence cannot explain all the bizarre phenomena of epidemics, and that it is necessary to admit, over and above the focus of infection, a general cause which hovers over all the individuals placed in this focus, an epidemic cause, a *quid divinum* or *ignotum* as has been so often repeated.

The *Medical Gazette* of Algiers reviews a recent work by M. Jules Girette, where this question of the epidemic influence is treated on the largest scale. This writer, by the very title of his work, Civilization and the Cholera, betrays that his views are liable to be all rather biassed by the idea that belief in contagion must tend to barbarize nations, and hence ought to be discountenanced on moral grounds. It is rather unfortunate that this initial bias should be so perceptible, for it somewhat tends to shake the reader's confidence in the complete impartiality of the author's statements. Yet various circumstances pointed out, concerning the march of the epidemic of 1865, along the shores of the

Mediterranean, seem certainly difficult to reconcile with the theory of the perfect efficacy of quarantine. "Greece and Sicily isolated themselves completely, and escaped the cholera. But so also did Corsica, which continued to communicate freely with the infected cities of Nice and Livourne, and only subjected vessels coming from Marseilles, where the epidemic was at its height, to a quarantine of three days. Salonica and Volo, unexpectedly exposed to the contagion, after a prolonged quarantine, nevertheless escaped. Neither Sarnsoum, nor Catourn, nor Dourgas, nor Varma were attacked by the cholera, although they were constantly visited by emigrant vessels. It scarcely touched Trebisond, traversed by hosts of fugitives *en route* for Persia. Yet all these ports had no other defence than a quarantine of from three to five days. At Malta, Beyrout, Dardanelles, and Odessa, the epidemic was communicated to the city by the lazaretto that professed to protect it. At Constantinople, a Turkish frigate evaded the quarantine, and imported the disease. Majorca, surrounded by a *cordon sanitaire*, attributed the cholera by which it was decimated, to some secret fraudulent importation, since no other cause could be discovered. The same with Alicant. At Enos the epidemic raged, and could be explained by no suspected communication. Trieste, spared up to the 28th of September, and believing itself secure behind a model lazaretto, awoke to find the cholera within its walls. Southampton, freely open to arrivals from Alexandria, did not register its first death from cholera until the 25th of September, nearly at the same time as Trieste, and two months after Marseilles."

M. Girette, however, takes great pains to trace the march of the epidemic of 1865, from its cradle, among the hordes of pilgrims to Egypt. M. Jobert, however, sanitary physician on board the Arethusa, who reviews the book, lays much more stress than the author upon the fact that some new and peculiar atmospheric conditions, or epidemic capacity, must have prevailed at Egypt during that year, since every year the pilgrims were in the habit of having the cholera at Hedjaz, but it was not communicated beyond their own camp. M. Jobert quotes with especial emphasis the description given from personal observation by M. Girette, of the state of things at the temple of Withoba, at Punderpoor, where men and women were crowded together by thousands, in a narrow court, awaiting their turn to enter the temple. Inside the little stone temple the same, and worse; the emanations from the bodies of the worshippers condensed upon the statue of the god, and the moisture was regarded as a miraculous sweat! The resident physician at Punderpoor believes that the first origin of the cholera is probably at this celebrated shrine.

To return for a moment to M. Rodet. He speaks hopefully of the good effects of the treatment suggested by Dr. Burg, and in 1865 experimented by M. Lisle, physician at the Insane Asylum at Marseilles. Upon the appearance of the epidemic in the asylum, M. Lisle had at first endeavored to combat its ravages by the ordinary method of diffusible stimulants. He lost twelve patients out of fourteen, a number much greater than the ordinary average, and whose excess is to be attributed to the much feebler resistance to the disease offered by the insane. Finally the servant of M. Lisle was attacked; he employed the same treatment, and with equal lack of success, for at the end of twenty-four hours all hope seemed to be lost. In this extremity he resolved to try Dr. Burg's prescription, and considerably to his surprise the woman recovered. He then applied the same treatment to the remaining patients in the wards, and the results surpassed his expectations. Among twenty-six men he obtained twenty-one recoveries, and among six women (including his servant), four; in all, twenty-five cures among thirty-two cases.

The following is the formula for the remedy that obtained such unlooked-for success:

Dissolve five per cent. of sulphate of copper in 150 grammes (about five ounces) of distilled water; and add to this 150 grammes of sugared water, together with 10 drops of Sydenham's laudanum.

A CASE OF OSTEOMALACIA.

At the Society of Medical Sciences at Lyons, was recently presented by M. Vérard, a most interesting case of osteomalacia. The patient, as usual, a woman, was thirty years old, and had been the victim of the disease for ten years at the time of her death, which occurred in an attempt at child-birth. I have been unable to find the details of the case as related by M. Vérard, having only at hand a subsequent report upon the case, made by Dr. Berne, surgeon at La Charité at Lyons.

In this report is only noticed, that the commencement of the disease had been characterized by sharp pains, which had been supposed to be rheumatismal; that the pregnancy had, as usual, greatly accelerated the march of the disease; that the diseased bones presented were all highly porous; that in the spongy tissue, the osseous trabeculæ had become rare, or had disappeared; the medullary spaces had united together, and in the hollow bones contributed to enlarge the medullary canal; that even in the cortical compact substance, the vascular canals were enlarged, and formed areolæ, which uniting transformed it into a spongy tissue of large network; which indeed was so general that the compact tissue had almost disappeared, and there only remained the superficial layer, which, moreover, was infiltered by a yellow, fatty, medullary substance; that, besides, in the parts of the osseous system which were the most altered, were discovered numerous cells resembling pus globules.

This last fact seems to confirm the opinion of Virchow, who ascribes osteomalacia to a parenchymatous inflammation, the immediate consequences of which are only an interstitial exudation, but the remote result is the destruction of the osseous tissue.

A chemical analysis of the bones was made, principally with a view of searching for lactic acid, and thus indirectly testing the theory* that ascribes the resorption of the lime salts to the presence of this agent. It was impossible to find lactic acid in the free state, for at the time the analysis was made, the bones had already submitted to maceration for several days in water saturated with marine salt, and the acid, if present, would necessarily be dissolved. But some lactates might still be left. To settle the question, the ashes of the calcined bones were treated with water, thus losing a considerable portion of their weight (0·42 gr. out of 0·99 gr. for the spongy substance, and 0·23 gr. out of 1·73 gr. for the compact). The filtrated substances, precipitated with nitrate of silver, gave 0·20 chloride of sodium in the first case, and 0·10 in the second. Remained 0·22 and 0·13 of residue, in which, if anywhere, the lactates were contained. In this residue, dissolved in distilled water, the presence of an organic acid was presently proved by the addition of a few drops of nitric acid, then lime-water, which formed a precipitate, proving that the nitric acid had found material to convert into oxalic acid, which produced an oxalate with the lime. Further examination showed that the solution did not precipitate with baryta-water, had no action upon lime-water until it had been treated with nitric acid, and gave a white

* Of MM. Marchand, O. Schmidt, and Otto Weber.

precipitate with concentrated acetate of zinc, whence the presence of lactic acid was conclusively proved.

The usual disproportion between the organic and inorganic materials of the bones was also shown by the analysis. The proportion in 100 of the inorganic matter instead of being 64, the normal figure for compact bone, was 41, and in the spongy substance not more than 18.

The proportion between the carbonates and phosphates remained the same, the former being one-tenth the weight of the latter.

M. Vérard very justly regretted that no experiments had been made to ascertain whether, in spite of the narrowness of the basin, the head of a fœtus could not have been made to pass, in virtue of the softness of the bones. The antero-posterior diameter of the inferior strait only measured from a centimètre and a half to two centimètres; but the bones were so soft, that the first placed in the pelvic cavity easily forced a place for itself. Dr. Berne thought that in a similar case, at a moment of *accouchement*, before the obstetrician should address himself to the cesarean operation, he should seriously consider whether the pelvic basin were not susceptible of enlargement by dint of pressure. In the case in question, I am unfortunately unable to tell what was actually done.

THE FUNCTION OF THE VASCULAR GLANDS.

At a recent séance of the Academy of Medicine in Belgium, Dr. Foisson read a paper, propounding a theory on the function of the vascular glands, that seems to me much the most ingenious and complete of any that has ever been advanced concerning them. This theory carries out the suggestion made by Broussais, who assigned to the spleen the function of deviating the blood from the stomach; so the thymus and thyroid, a similar rôle for the respiratory organs. This idea, however, being based upon no serious proof, passed unperceived. But M. Foisson has greatly enlarged and strengthened it in his essay, of which I shall endeavor to give you an idea.

The general theory of derivation is the following: All organs submitted to alternations of action and repose, require a greater amount of blood during the first than the second period. The variations thus necessitated in their circulation, are effected by an agency independent of the general circulation, namely, the appropriate vascular glands, that act by driving the blood away from the organs when they have no need of it.

The only organs in adult life, engaged intermittently in active functions, are the muscles, stomach, brain, and uterus.

The muscles, when acting separately, mutually derive the blood from one another, and when they act all together, the heart quickens its action, and sends the excess of blood required. Their variations, therefore, depend directly on the general circulation, and they have no need of special apparatus.

But the stomach is essentially intermittent in its activity. The secretion of gastric juice evidently demands a large amount of blood, to judge from the size of the arteries distributed to its walls. During the intervals of digestion, these arteries are tortuous, and comparatively little blood passes through them. The blood from the cœliac axis being mainly distributed by the splenic artery to the spleen, the tortuousness of this splenic artery may be supposed to be unfolded at an opposite time from that in which the gastric arteries grow straight.

The thyroid gland is the derivative reservoir for the blood going to the brain. This blood arrives at the thyroid from the superior thyroidien given off from the internal carotid—and the inferior thyroidien, that springs from the subclavian close by the origin of the vertebral, so that by a double route the circulation of the thyroid can affect that of the encephalon. In virtue of that same connection, between the thyroid and the brain, do persons affected with goitre so often become cretins; the exaggerated development of the thyroid interferes with the nutrition to the brain, and the more important organ is actually starved out by the fraud of the less, which seizes its supplies *en route*. Finally, for the uterus, the mammary glands perform the office of derivation, and, after parturition, when the uterus must retract, and has no further need of the expensive nourishment upon which it has subsisted during pregnancy, the epigastric arteries, prepared for the task by the development they have experienced during the last months of this period, intercept the supply of blood going to the uterus, and convey it to the glands, by means of their anastomoses with the mammary arteries. Among animals in whom the mammary glands are abdominal, the epigastric artery supplies them directly. To this extremely suggestive interpretation of the well-known facts of the case, one difficulty may be addressed. If the extra nutrition of the uterus and mammary glands is carried on at alternate periods, how does it happen that the glands increase during pregnancy? This fact, however, is really provided for by the theory which admits that the satellite organs do increase coincidently with their principals, if only for the sake of being at hand, and in good condition, to receive the brunt of their circulation when the functions of the principal organ is intermittent; but that in addition to this parallelism of development, comes the alternative, or contrast, at the moment when the principal organ subsides into inactivity, and the satellite starts into full activity.

For explanation of the office of the thymus gland and supra-renal capsules, the theory is identical, but applied as it were in an inverted fashion as respects chronological order. The lungs and kidneys do not function at all* during fœtal life, and hence have need of only so much nutritive fluid as is required for their growth. But as they begin to act at the very moment of birth, the new supplies necessary for the maintenance of their functions must be stored up close at hand, ready to be turned into their future channels. For this purpose the thymus gland and supra-renal capsules are contrived. The blood during fœtal life is directed towards them, as it were next door, but at the moment of birth the current is turned into the neighboring arteries, and from that moment the fœtal organs begin to waste and gradually disappear.

The thyroid gland also, though in action throughout life, is much required during infancy, since the brain at that period, as far as regards its intellectual functions, is in a quiescent or at least passive state, consequently the thyroid gland of children is proportionately much larger than in adults.

M. Foisson refers to the characteristics common to the structure of all the vascular glands, as tending to confirm his theory. Huschke and Kolliker agree in recognizing in all these organs the existence of:

1. A foundation system of trabeculæ, serving for a support to the vessels.

2. Vesicular cavities occupying the interstices left between the trabeculæ.

3. The presence in the cavities of a liquid charged with globules, and the absence of any efferent canal. Nothing in this structure suggests the idea of a secre-

* This is the remark of the author. But I believe it is not strictly correct for the kidneys, since the bladder is found to contain urine before birth.

tion appropriated to the perfectionment of the blood or lymph, while it is on the contrary marvellously adapted for the purposes of derivation.

The entire theory is resumed in the following propositions:

1. All the organs of the economy consume during the periods of their activity an amount of blood more considerable than that required in repose.

2. In the normal state, the heart sends at each moment the same quantity of blood in every branch of the arterial tree.

3. The blood which arrives at organs in excess during their period of repose, is received by special organs called *derivators*.

4. The function of derivation may be performed without the intervention of an organ exclusively devoted to the task, as in the case of the mammary glands.

5. Every organ whose function is intermittent, possesses an apparatus for derivation.

6. Derivation is not only arterial, but sometimes venous, as when the spleen receives the *trop plein* from the portal vein, or the thyroid, during muscular exertion, from the engorged jugulars.

7. Derivation is a complementary function of the circulation, and necessary to a regular distribution of the materials of nutrition and secretion. At the same time it is not absolutely essential to life, so that in the lower animals any of the vascular glands may be extirpated with impunity.

8. Derivation is explained by the following law of physics: When a pipe traversed by a fluid is divided into two branches, that of the two in which the current is the most rapid receives a greater quantity of liquid than the other.

This theory is so perfectly captivating to me, that as yet I have not been able to imagine any serious objection to its soundness. Perhaps you or your readers may be more critical, and I submit it to your judgment.

UNION BY FIRST INTENTION AFTER LITHOTOMY.

Professor Bouisson, of Montpellier, is at present writing a series of articles in the *Montpellier Médicale*, upon union of the wound by first intention after the operation of lithotomy. The Professor not merely believes this to be possible, and in his first paper adduces four cases in proof of his assertion, but engages to show how this very desirable result can be secured. Of these four cases, the first was that of a young man who had been treated for some time with elastic bougies, in the hope of sufficiently dilating the urethra to admit of the operation of lithotrity. All at once, however, the patient became unquiet and irritable; an obstinate spasmodic condition of the canal joined itself to the organic retraction, and forced the surgeon to abandon all hope of crushing the calculus, and an operation for lithotomy was decided upon. Owing to the presumed smallness of the stone, the median incision was selected. The operation was performed on the 16th of December, and encountered no serious difficulties. An incision of three centimètres practised on the median line of the perineum easily attained the urethra. After division of the cutaneous and cellular layers, the membranous portion being directly divided, the length of the left edge of the catheter which had been introduced in the urinary canal to serve as a guide, a lithotome was introduced, the catheter withdrawn, the finger, gorget, and forceps successively introduced into the bladder, and the calculus seized and extracted.

The calculus was spheroidal, with irregular surface, so compact and hard that the operation of lithotrity would have beeen very difficult. A vesical injection terminated the operation, which had been performed with the assistance of chloroform. The knees of the patient were then drawn together, and maintained in an elevated position by a cushion placed underneath; a calming and diffusible draught was administered; the day passed without fever or vesical pain; the patient vomited twice; in the evening a little urine escaped by the natural passage. The next day reddish urine was passed naturally, also a very small amount escaped at the wound, whose appearance was good. During the two following days also the local and general phenomena were satisfactory; the urine nearly entirely passed by the urethra. The wound closed without suppuration, and by the eighth day was *completely cicatrized by first intention*. The cure was permanent.

In the second operation performed by M. Bouisson, the patient was sixty-four years old, and the bladder contained six calculi and was completely paralyzed. After the operation, whose details I will not repeat, the persistent retention of urine, which did not even escape by the wound, rendered it necessary to leave a sound permanently in the bladder, for the accumulation caused much pain and suffering to the patient. By this means also the urine was completely turned away from the wound, a circumstance which undoubtedly favored its union, which was effected in six days, by first intention, without any trace of inflammation or infiltration. In this case also the median incision had been practised. The third, the same form of the operation. The subject was sixteen years old; the calculus, though hard and voluminous, was ovoid, and presented itself to the forceps by its most favorable diameter, so that it was extracted without difficulty. After the operation, the adduction of the thighs was secured by means of an apparatus, so that the lips of the wound were brought in contact, and the dorsal decubitus strictly enjoined. The first day only theurine escaped by the wound; after that the patient was able to urinate voluntarily. Even after the subsidence of the swelling around the lips of the wound, which might at first have opposed the escape of the urine, that liquid continued to traverse the natural passages, and owing to this fortunate circumstance the wound was cicatrized by the sixth day. Neither infiltration, nor ecchymosis, nor suppuration supervened, and the cicatrix remained perfectly solid. The fourth operation, with the medio-lateral incision, was performed on a child of six years old, who had suffered from painful micturition from the age of two years. In this case the first sounding had failed to discover the calculus, and although that was distinctly perceived at the second examination, it seemed again to disappear at the moment of the operation. Nevertheless, M. Bouisson made the incision. The posterior radius of the prostate gland seemed so short, in consequence of the flattening of this organ, that, having practised the median section of the skin as far as the urethra, M. Bouisson judged it prudent to incline the lithotome in the direction of the oblique radius of the prostate, in order to avoid the rectum, and to limit this oblique section to the gland, so that the incision represented a broken line whose first part was straight, and the second oblique. This opening, more than sufficient for the extraction of the calculus, gave issue to a certain quantity of urine, which carried the stone along with it into the very grasp of the forceps. The calculus was the volume and shape of an olive; mammillated, reddish-yellow, and composed of uric acid. The whole operation only occupied three minutes from the moment of the incision to the extraction of the stone.

In consequence of the inclination of the lithotome, a branch of the perineal artery had been divided, giving rise to considerable hæmorrhage, an accident that

had been entirely avoided in the other operations. The hæmorrhage was arrested by torsion of the vessel, but returned some hours after the operation, to be finally vanquished by compression and the application of ice. This was the only notable effect of the operation. The urine escaped by the wound during the evening and in the night; but after the first day the passage of urine ceased to be continual, and came under the influence of vesical contraction. Towards the end of this day a part of the urine passed by the urethra, and from the fourth day no more escaped from the wound, which united without suppuration, and without the occurrence of either sanguine or urinary infiltration. By the eighth day the cicatrization was complete.

All these cures were obtained by the perineal operation. M. Bouisson thinks that such happy results could rarely be achieved when the hypogastric incision was practised. In succeeding papers he hopes to develop further views suggested by the interesting observations of which I have related the summary.

NEW APPARATUS FOR IRRIGATION OF THE EYE.

Dr. Amable Cade, of Saint Andéal, also makes a communication to the *Montpellier Médicale*, concerning a new apparatus devised by himself for securing continual irrigation of the eye after the operation for cataract. This is composed:

1. Of a hemispherical reservoir, of a capacity of nearly a quart, with an opening at the top, and capable of being suspended over the head of the patient.

2. Two supra-ocular recipients, of lozenge shape, each furnished with two little handles, destined either to fix the apparatus before the eyes by the aid of a circular band, or to keep in place the two recipients when both eyes have been operated the same day. Their posterior side is made of gold-beater's skin, which ought to be placed in immediate contact with the closed eyelids.

3. Two tubes, communicating between the reservoir and the recipients. These tubes are furnished with screw joints, which permit the suppression of one of the recipients when only one eye is operated.

4. Little pieces of sponge loosely introduced in the communicating tubes, to prevent the passage of the water, except drop by drop, every second in ordinary cases. These sponges may be removed in case of imminent danger from violent inflammation, when a rapid current of cold water is needed.

5. Two discharging tubes, a yard and a half in length, destined to conduct the irrigating fluid from the recipients to a vase placed by the bedside.

By means of this apparatus, Dr. Cade has already performed eight operations for cataract with the most complete success, in some cases warding off a commencing phlegmonous inflammation, that threatened to become a terrible complication. P. C. M.

Operation for Anteflexion of Uterus.—Dr. J. C. Nott, of Baltimore, suggests a modification of Dr. Sims's operation for the relief of dysmenorrhœa dependent on anteflexion of the uterus. After making the bilateral incisions through the neck, he allows the hook to remain in the *anterior* lip while the posterior is cut off by curved scissors. By this expedient the canal of the neck is kept open, and after the internal posterior longitudinal incision the sponge-tent is *at once* and easily introduced. Any vessels divided should be immediately ligated. He suggests also an alteration in the tents, by which they are rendered firmer, more cleanly, and more rapidly effective.—*Am. Journal Med. Sciences.*

MEDICAL MATTERS IN PHILADELPHIA.

[FROM OUR SPECIAL CORRESPONDENT.]

VISIT OF T. SPENCER WELLS, OF LONDON, TO THE CLINIC OF THE JEFFERSON MEDICAL COLLEGE,

AND REMARKS BY THAT GENTLEMAN UPON

OVARIAN TUMORS.

To the Editor of the Medical Record.

Sir—With the approach of autumnal changes, greater activity is being exhibited in our medical circles. The summer months, not very warm, have been marked by a most unusual deluge of rain, which has kept the streets of our city comparatively clean, despite the neglect of "contractors," and as a consequence conserved the health of our inhabitants. Such a healthy season as the summer just past has been, has not been known here for years; some go so far as to say that there never has been such a healthy season. The mortality reports have shown a marked decrease in the proportion of deaths as compared with the years more immediately preceding, notwithstanding an evident increase of population. Vernal complaints have not been near as frequent as usual, nor have there been the usual proportion of protracted illnesses. Bilious remittent fever, bronchitis, and pneumonia seem to have been the most frequent disorders, and this has been the result of hospital as well as of private practice. A number of physicians have remarked this season a greater amount of periodicity in disease generally this season, as if a malarial element pervaded the locality, and as a consequence there has been more frequent occasions for the exhibitions of quinine in addition to other treatment. As a consequence of the mildness of the temperature there have been remarkably few cases of insolation during the summer.

The Colleges are open again, finishing their summer courses, and are well attended by the "spring" classes, as well as by a sprinkling of first-course men, who are slowly arriving.

Most of the medical societies have resumed their meetings, and are preparing for energetic and instructive employment for the winter. Medical publishers, too, are getting ready to offer a valuable file of literature the coming season. The enterprising firm of Lindsay & Blakiston are issuing from their press an exceedingly valuable catalogue of new books and republications. Of these are just out—"Harris's Dictionary of Dental Surgery," a work which has been out of print for four or five years, and a republication of the "Biennial Retrospect of Medicine, Surgery, and their allied Sciences," for the New Sydenham Society, 1867, edited by Powers, Anstie, Holmes, and other well-known authorities. They have also nearly ready, and shortly to be issued, a work on "Epidemic Meningitis, or Cerebro-Spinal Meningitis," from the pen of Dr. Alfred Stillé, Professor of the Practice of Medicine in the University of Pennsylvania; one from the pen of Dr. J. Solis Cohen, of this city, on "Inhalation: its Therapeutics and Practice;" a new edition of "Diseases and Accidents incident to Women;" Hufeland on "Prolonging Life;" Taft's "Operative Dentistry," etc.; and they are preparing, with a great deal of care, the first volume of "Reports of Cases and Clinical Lectures," by the Medical and Surgical Staff of the Pennsylvania Hospital, with papers from the pens of Drs. Gerhard, Levick, Meigs, Da Costa, Hewson, Morton, Hunt, and Agnew. This work is to be abundantly illustrated, and to be issued about New Year, in the highest style of the art. The volume is looked for with peculiar eagerness by our city practitioners, who all feel attached to the old

institution, the memory of whose hard benches involuntarily calls the palm to the breech, and will doubtless be hailed with equal pleasure by all who have frequented the old amphitheatre.

The great event of the week has been the visit of Dr. SPENCER WELLS, the British ovariotomist, to the clinic of Jefferson College, on Saturday last, and his remarks to the class in connection with the diagnosis of an abdominal tumor which was examined by him upon the occasion. The brothers ATLEE were present with the distinguished guest, who had just witnessed an operation of ovariotomy by Dr. WASHINGTON L. ATLEE, of this city, who has performed the operation more than one hundred and sixty times. Prof. Gross, in introducing these gentlemen to his class, took care, in commenting upon the operation of ovariotomy, to allude to its American origin, and to substantiate the claims of Dr. JOHN ATLEE, of Lancaster, Pa., who was present, as the first surgeon who had ever performed the operation of removing both ovaries upon the same occasion; this patient was operated upon in 1843, and is still living.

After attending to a few urgent cases to whom promise had been made to attend to them that day, Prof. Gross yielded the balance of the hour to Dr. WELLS, who then proceeded to examine the patient, who had been provided for that purpose. This was a negro woman, æt. 43, widowed, and who had carried an abdominal tumor for fourteen years. The patient was placed in the recumbent position, with the head and shoulders elevated, the tumor being uncovered throughout its entire extent without exposure of any other part of the person. Dr. Wells stated that it was his usual plan to expose the tumor in this way and secure a good view of it, before asking any leading questions from the patient, and he thereby avoided loss of time which might be occupied in the recital of unnecessary history, and elicited information on such points only as might be pertinent to the case. It was an interesting fact in connection, that he had never met with a case of ovarian tumor in the negro, though he had seen one in a creole who had come from New Orleans and in a mulatto woman from Jamaica. This infrequency might he accounted for by the limited number of black people in the British Islands, though his friend Dr. Washington L. Atlee, of Philadelphia, who was present, and whose experience in ovarian tumors was equalled by no other American surgeon, informed him that fibroid tumors of the uterus were much more apt to be met with than ovarian tumors in the negro race. The fact of the patient being a negro would in a measure deprive him of one of his aids to diagnosis, on which he placed considerable importance. He referred to the complexion of the patient. Whenever a lady with an enlarged abdomen presented herself in his consulting apartments, the first thing he did was to notice her complexion; if this was healthy or florid he always suspected he had a tumor connected with the uterus to deal with, but if it were pallid, yellowish, or waxy, his mind instantly reverted to the probability of the tumor being ovarian. Emaciation too was more generally apt to be associated with ovarian tumors, and in the patient about to be examined there is a general appearance of health which would not lead to suspicion of the existence of serious disease were it not for the presence of the abdominal enlargement. After gaining a general idea from the appearance of the tumor in a state of rest, he then proceeded to a physical examination; and the first step is to measure the tumor by means of the tape-measure; the first measurement is taken round the body at the level of the umbilicus; the second is a vertical measurement in front, and is taken in two steps, one being from the edge of the ensiform cartilage to the umbilicus, and the other from the umbilicus to the pubic symphysis, which shows whether the tumor occupy more of the upper or more of the lower portion of the abdomen; next, an oblique measurement would be taken from each superior spinous process of the ilium to the umbilicus, demonstrating whether the tumor occupied a position more to the right or to the left, and was therefore more likely to be connected with one ovary than the other. The measurements being concluded, his next step in the examination is palpation of the tumor, to judge of the sense of resistance, of the existence of fluctuation, of the nature of such fluctuation if present, and of the size, consistence, and surrounding attachments of the tumor. If by slightly filliping the abdomen, distinct evidences of fluctuation follow, as shown by the movement of a wave of liquid beneath the integument, readily distinguished by the eye, even at a considerable distance, as occurred in the instance under examination, then he inferred that the water thus seen was not contained in a cyst, for the walls of a cyst are too firm to permit of the production of such distinct rippling, and his conclusion would be that the fluid was immediately beneath the abdominal integument, that is to say, free in the peritoneal sac, and therefore surrounding the tumor. The next step in the examination is to determine the boundaries of the tumor, and these could be marked out by pressing the walls of the abdomen in with the ends of the fingers until the edge of the tumor was felt, and then carrying the fingers around the tumor and thus determining its contour. Then succussion was performed on each side of the tumor, first with one hand and then with the other, to determine the existence of any fluid within it which would be signalled if present by the transmission through the mass of a sense of fluctuation from one hand to the other. In the instance under examination no such sense of fluctuation within the walls of the tumor could be perceived. The next thing was to lift up the tumor through the abdominal walls, to get an idea of its weight, density, and amount of attachment to surrounding structures. In the present instance the tumor could be lifted freely in every direction, showing that there were no serious attachments, and the abdominal walls could be readily lifted from the mass, and without producing any tension upon the umbilicus, showing that there were no adhesions in this direction. Then, he proceeded to pass the fingers around the edges of the tumor and under them, so as to judge of the integrity of outline of the mass; and in the present case he distinguished here and there small outgrowths of the size of a marble or walnut, particularly at the lower portion of the tumor as it approached the pelvis. The existence of these nodulations is extremely rare in cases of ovarian tumor, but they are not uncommon in fibroid tumors of the uterus. This circumstance, the fact of the patient's appearance denotive of comparative health, together with the absence of œdema of the lower extremities, would lead him to the inference that the case under examination was one of fibroid of the uterus, and not of ovariant umor. A further method of continuing the diagnosis consisted in auscultating the tumor. In fibroid tumors of the uterus there can almost always be detected a vascular murmur, sometimes much like the murmur heard through the placenta, which is not heard in ovarian tumors. Applying the stethoscope in the present instance, no such decided vascular murmur could be heard, but there was a distinct sense of propulsion communicated to the ear, and synchronous with the pulse, which was due to the transmission through the tumor of the pulsations of the abdominal aorta. A vaginal examination was then made, resulting confirmatively with the diagnosis arrived at by external examination of the tumor. This was inferred, princi-

pally because the cervix of the uterus was beyond the reach of the finger. When there exists a fibroid tumor of the uterus, the enlargement of the fundus carries the neck of the womb up out of the pelvis, and a vaginal examination, as in the present case, is apt to reveal an empty pelvis. This is not usually the case in ovarian tumor, though sometimes under such circumstances the neck may be beyond reach, but usually a portion of the ovarian tumor may be felt as a fluctuating mass between the cervix and the bladder, or between the cervix and the rectum. Still another aid to diagnosis exists in the introduction of the uterine sound. If the sound can be passed several inches into the organ, it is confirmative of enlargement of the uterus, but often when such enlargement exists, the sound cannot be introduced in consequence of the tortuousness of the canal of the cervix; and therefore the negative evidence afforded from the sound is not to be always taken into consideration as proof of non-enlargement of the uterus.

Having determined the diagnosis, the question arises as to the treatment. In a case like the present it must be palliative, upon general principles to meet indications as they call for interference. Extirpation of such a tumor is sometimes performed, but the results are eminently unfavorable. Five such operations had been performed by the lecturer, but they had terminated fatally in every instance, probably because, in some degree they were not cases favorable for surgical interference. The operation has, however, proved successful occasionally, but not as a rule. He would not, therefore, advise the removal of a fibroid tumor of the uterus unless the life of the patient were in imminent peril from impaction of the rectum or other cause, and operative interference presented the only chance of relief.

Dr. Wells then proceeded to exhibit the instruments he had devised for drawing off the contents of an ovarian cyst previous to its removal, and for securing the pedicle afterwards. He had found an inconvenience in the use of the ordinary trocar and canula from the escape of fluid between the walls of the cyst and the canula during the interval between the puncture and the withdrawal of the trocar. This he believes he avoids by the use of a hollow trocar, permitting the escape of the fluid from the very instant of puncture. The instrument presented is of large size, probably admitting the end of the finger, and protrudes beyond a canula in the shape of the nib of a large quill-pen. As soon as the instrument has been plunged into the cyst, and while the fluid has already begun to escape, the trocar can be withdrawn within the canula, avoiding the chance of subsequent injury. The canula is encircled by two semicircular, three-pronged vulsella, which are intended to seize upon the walls of the cyst, so that they can be withdrawn from the abdomen during the evacuation of their contents. To facilitate this evacuation, and to avoid the noise or other embarrassment which occasionally produces an unpleasant effect during the draining of the fluid, he has attached to his canula a long rubber tubing of large size; the tube consists of two layers of india-rubber, enclosing a spiral wire which keeps the tube pervious. His clamps for securing the pedicle consist of two stout parallel curved plates of steel, serrated on their opposing surfaces and admitting of very great compression by means of screws on the outside; they have movable handles which can be withdrawn after the pedicle has been secured, and their curved form renders the walls of the abdomen more tolerant of their pressure during the separation of the pedicle. Where the pedicle is too short to be secured in this way, he employs another instrument composed of two metallic blades shielded beneath with ivory to prevent the passage of heat to the tissues between which the pedicle is grasped, and then all that portion which protrudes beyond the instrument is seared off with the hot iron, the abdomen being protected from contact with the cautery by a vertical shield attached to one of the blades of the instrument. After all the tissue above the level of the instrument has been destroyed, the blades are gently separated to avoid tearing the attachments which have adhered to the instrument during the cauterization; as the blades are separated, any hæmorrhage that occurs is immediately controlled by ligature; and finally the pedicle is allowed to become retracted within the peritoneal cavity, and the incision in the integument is closed.

Dr. Wells stated that he had performed the operation of ovariotomy in all 228 times, and with the following result: of the first hundred cases, 66 recovered and 34 died; of the second hundred, 72 recovered and 28 died; and of the last twenty-eight cases, 24 recovered and 4 died; in all 162 recoveries and 66 deaths, or a general mortality of a little more than twenty-nine per cent. He had removed both ovaries in seven cases, four of which recovered and three died.

With regard to the mortality of the operation, Dr. Wells did not consider it greater than in other serious surgical operations, such as amputation at the hip, ligation of the iliac artery, the operation for strangulated hernia, and the like; besides which it must not be forgotten that the operation is one of recent origin, and that there is not therefore in this department of surgery that accumulation of experience which serves as a guide in other operations. He believes, too, that as surgeons become more familiar with the proper selection of cases, the mortality would gradually decrease in accordance with previous experience in the history of surgical operations; while here, as elsewhere, a certain number of operations are performed at the urgent solicitation of the patient, even against the judgment of the operator. He alluded to mistakes likely to occur in the diagnosis of ovarian tumor, embarrassments which present themselves unexpectedly during the progress of the operation, and occasionally preventing its completion; but he did not think these mistakes were more frequent than mistakes which sometimes occur in all branches of surgery, despite the exercise of the greatest care and judgment, and he instanced the circumstance of lithotomy having been occasionally performed without the discovery of a calculus, the puncturing of an aneurism instead of an abscess, as parallel cases to those in which a fibroid or other tumor has been mistaken for an ovarian cyst, and thus led to an operation which should not have been undertaken; but he firmly believed that as science advanced, these mistakes would gradually become less frequent, and be eventually expunged from the history of ovariotomy.

The above *resumé* from memory will enable your readers to judge of the practical manner in which the subject was handled, and your correspondent only regrets that he did not take notes, so as to have given a more extended report for your lecture column; but the fact is that he became so interested in the gentleman's manner that he forgot all about notes.

Yours truly,

C. J.

PHILADELPHIA, Sept. 16, 1867.

STILL ANOTHER ALKALOID OF OPIUM.—Messrs. T. and H. Smith, of London, have found a new alkaloid in opium, to which they have given the name of *Cryptopia*. These chemists, however, obtained only five ounces of the *muriate of cryptopia* from out of four tons of opium. The primary form of the crystals is a hexagonal prism. The chemical formula is as follows: $C^{33}H^{21}O^{6}N$.

A QUESTION OF PRIORITY.

To the Editor of the Medical Record.

In your issue of Sept. 1, 1867, is an article on the treatment of hip-joint disease, by Dr. Chas. F. Taylor, which contains a sentence which deserves a comment. Dr. Taylor says, "In 1860, before I had ever treated a case of hip-disease, my attention was called to the subject, in consequence of the discussions going on at the time. I then devised the short instrument, which has since, for some unaccountable reason, been labelled with Dr. Lewis A. Sayre's name."

This gentleman made the same charge in the *American Medical Times*, of July 20, 1861, and which I corrected in the following number, of July 27, 1861, by the letter of Dr. Erskine Mason, stating that I had used the short splint in Bellevue Hospital in Sept., 1860, up to which time Dr. Taylor now states in his last paper he had never treated a case of hip-disease.

Why he repeats this error, which he has once admitted and apologized for, I leave for himself to explain.

The following is from the *American Medical Times* of July 27, 1861, and speaks for itself:

"Correction.

"*To the Editor of the American Medical Times:*

"795 Broadway, New York, July 24, 1861.

"Sir—In your issue of July 20th, in an article on 'Improved Splint for counter-extension in Morbus Coxarius, by Dr. Charles F. Taylor,' in which he states that he constructed an instrument in the latter part of last year, with a branch passing from the external splint over just above the knee, to the inside of the thigh, etc., and in the concluding paragraph of his article, after claiming various improvements, etc., says: 'I am forced to do this from the fact that the *Medical Times*, in its issue of June 29th, had an instrument figured as the improvement of Dr. Sayre, which the reader cannot have failed to notice, is, so far as the contrivance for receiving the adhesive strap from the inside of the thigh, substantially identical with the one here described. This improvement was first shown by me to Dr. Sayre after I had used it several months, and he has adopted it without giving me proper credit.'

"Dr. Taylor first showed me his instrument about the 1st of February, 1861, whereas it will be observed, by the following correspondence, that my instrument was exhibited at Bellevue Hospital at the time of my lecture on Hip-Disease, in December, 1860, and I had constructed it some time previous, at the suggestion of Dr. Mason.

"As the lecture was not published until June 29, 1861, it is possible that Dr. Taylor fell into his error by not observing the date of its delivery.*

"I called upon Dr. Taylor as soon as I had read his article, knowing that he would correct the error, as soon as it was explained to him, but finding him absent from the city, and that he would not return for some weeks, I have deemed it but justice to myself to correct this false statement.

"'795 Broadway, July 22, 1861.

"'Dr. Mason, House Surgeon, Bellevue Hospital:

"'Dear Sir—Will you be kind enough to give me the date of the case of Morbus Coxarius, in Dr. Crane's wards, and for which you suggested to me to alter my instrument so as to make extension from above the knee only, and also the date of my lecture on that subject, in which I exhibited the improved instrument.

"'Respectfully yours, etc.,

"'Lewis A. Sayre.'

"'Bellevue Hospital, July 23, 1861.

"'Dr. Sayre: *Dear Sir*—The time I first made the suggestion to you to make the extension from above the knee in your apparatus, for the treatment of hip-disease, was about the middle of September, 1860.

"'The apparatus, thus modified, you showed to your class at Bellevue Hospital the middle of December, 1860.

"'Yours respectfully,

"'Erskine Mason,

"'House Surgeon.'

"Further comment is unnecessary.

"You will oblige me by giving this an insertion in your next issue.

"Respectfully, your obedient servant,

"Lewis A. Sayre."

Some weeks after the publication of this correction, Dr. Taylor, on his return to the city, called at my office, and apologized for the error, and regretting the injustice he had done me, promised to publish a correction.

For some reason or another this promise has obviously never been fulfilled.

By reference to the dates, in the two articles of Dr. Taylor, in one of which he states that he constructed his instrument in the latter part of 1860; and in the other that *he had used it several months* before he showed it to me, would certainly place the time of my seeing his instrument some months after January, at which time, as will be seen by the note of the Editor of the *Medical Times* my lecture was in the hands of the printer, and the instrument had been used some months before.

Yours respectfully,

Lewis A. Sayre, M.D.

285 Fifth Avenue, New York, Sept. 5, 1867.

* It is but proper that we should state that the lecture of Dr. Sayre has been in our possession since the early part of January, and that its publication was delayed by a pressure of matter.—*Ed. Amer. Med. Times.*

ACTIVE VENTILATION.

A new method.

To the Editor of the Medical Record.

Sir—On a close morning, an apartment where several persons have slept may be opened to the fullest extent of all the windows and doors, and yet so slow is the atmospheric diffusion that, on entering such a room several hours later, you would at once say "this air is unfit for respiration."

Wind-sails are often of great service in driving out the stagnant air from between the decks of vessels, but these are as dependent upon the wind as are the vessels themselves, but in the exceedingly simple method which I am about to propose we actually *raise the wind* by which we effect the good result.

It is by *gently swinging all the doors back and forth upon their hinges.* The thoroughness of this method may be demonstrated by placing a feather in a distant part of the room, and if you please, under or behind some piece of furniture where you would least expect it to feel the influence of your fan; after one minute's effort, look for the feather. Again, shut all the doors but one, and as you move that one observe that the distant windows of the apartment "rattle," and the curtains *swing* synchronously with your own efforts. This method of ventilation seems especially valuable for all sleeping rooms, for tenement-houses, basements, clothes presses, closets, or any other places where the atmosphere is not readily changed by draughts or currents. Its

advantages are too obvious for serious argument, but the process is so exceedingly simple that it will be neglected and forgotten. Were it some great thing, attended with parade and expense, we might hope for its general adoption. But for this consideration I would hardly say of my own thought that I regard it as an important practical hygienic suggestion which *ought* to increase the longevity of our race. The idea may have occurred to others —'twere strange if it has not—but I would make it the property of every man, the custom of every family, a blessing to every age.

Truly yours, J. H. HOBART BURGE, M.D.

60 COURT STREET, BROOKLYN, N.Y.

New Publications.

BOOKS AND PAMPHLETS RECEIVED.

A DICTIONARY of Medical Terminology, DENTAL Surgery and the COLLATERAL SCIENCES, by CHAPIN A. HARRIS, M.D., D.D.S., Prof. of the Principles of Dental Surgery in the Baltimore College, etc., etc. Third edition carefully revised and enlarged by FERDINAND J. S. GORGAS, M.D. D.D.S., Prof. of Dental Surgery, Baltimore College. Philadelphia. Lindsay & Blakiston, 1867.

A BIENNIAL RETROSPECT OF MEDICINE, SURGERY, AND THEIR ALLIED SCIENCES, edited by MR. H. POWER, DR. ANSTIE, MR. HOLMES, MR. THOMAS WINDSOR, DR. BARNES and DR. C. HILTON FAGGE, for the New Sydenham Society. Philadelphia: Lindsay & Blakiston, 1867.

IS IT I? A Book for every man. By HORATIO R. STORER, M. D., of Boston, Vice-President of the American Medical Association. Boston: Lee & Shepard, 1867.

Medical Items and News.

DR. H. KNAPP, PROFESSOR OF OPHTHALMOLOGY in the University of Heidelberg, is now on a visit to this country. He is one of the well-known authorities on eye disease in Germany, and strangely enough, expresses the same opinion concerning the facilities for medical study in this country as does Spencer Wells, quoted in another place. We take pleasure in stating that the distinguished professor intends at some future time to give us a practical article for our columns, on a subject connected with his specialty.

DR. B. A. CLEMENTS, Surgeon, U. S. A., according to the official accounts, is slowly recovering from an attack of yellow fever, contracted in the line of duty at New Orleans, La.

DEATH OF PROF. ROBERT WATTS.—At the moment of going to press we are informed of the death of our cherished friend, Dr. Robert Watts, Professor of Anatomy in the College of Physicians and Surgeons, in this city. This event, which we announce with no ordinary feelings of sorrow, occurred at Paris, France, on the 8th ultimo. An obituary notice of the deceased will appear in our next issue.

DEATHS AMONG U. S. A. SURGEONS IN THE LINE OF DUTY.—Nine surgeons in the United States service have died during the past month in the cholera and yellow fever localities of the West and Southwest. This is more than the usual mortality in that branch of the service for an entire year.

A NEW PARISIAN SENSATION.—Paris is just now in the enjoyment of a new sensation in the person of the Zouave JACOB (trombone-player), who *cures* the paralytic, the blind, and the bed-ridden generally, by a few energetically spoken phrases. He comes to Paris late in the afternoon, after giving a sitting of consultations at Versailles. The most remarkable part of the miracles wrought by him is the circumstance that he receives no fees, and cures without even the pretence of infinitesimal doses. JACOB is a general practitioner, and claims to be equally at home in every department of medicine.

THE MOTHER THE BEST NURSE.—The authorities at Munich for some years past have required that in all cases of children dying in their first year, the parents should declare whether or not the infant had been suckled by the mother. A statistical table of the last two years shows that out of 100 deceased 88 were not so brought up.

MORTALITY FROM SCARLATINA IN ENGLAND.—The average amount of scarlet fever that constantly exists in England may be estimated from the fact that in the twenty-one years from 1838–42, and 1847–62, the deaths numbered 910,720, or 14,796 annually. In fact scarlet fever is nearly as fatal as the entire class of fevers summed up by the Registrar-General under the generic term "typhus." In 1863 the total deaths from scarlet fever were 30,475, or 148 per 100,000 population. The annual average death-rate from this malady in London during the twenty-six years ending 1862 was 83 per 100,000 population. The mortality ranged from 32 in 1841 to 174 in 1863. In the quinquennium, 1839–43, the yearly average was 78; in that of 1844–48, it rose to 88; in that of 1859–63 it increased to 115; the death-rate of 1863 being 174, or more than double the average of the twenty-six years, 1838–64.

The census of 1860 shows that the total number of deaths from scarlatina in the United States in that year was 26,393.

NEW YORK MEDICO-LEGAL SOCIETY.—This society is now in active operation, and we shall endeavor from time to time to keep our readers informed of its doings. Dr. Wooster Beach, Jr., is the President, and Dr. Leo is the Secretary.

THE TRAFFIC IN COCCULUS INDICUS.—50,000 pounds of cocculus indicus were imported from India to England last year—a sufficient quantity to drug 120,000 tons of beer.

SULPHATE OF SODA AS A REMEDY FOR MACULÆ OF THE CORNEA.—Dr. De Luca reports to the French Academy of Sciences that sulphate of soda, which has the property of maintaining the fibrin of the blood in a fluid state, may be used with success in removing these spots. The best method of using it is to reduce the salt to a fine powder, and drop a pinch of it into the eye of the patient while in a horizontal posture—the salt is soon dissolved in the liquids of the eye.

BEER VERSUS BREAD.—The amount of nutriment contained in beer is generally greatly over-estimated. Leibig asserts that in 1,460 quarts of the best Bavarian beer there is exactly the nourishment of an ordinary two and a half pound loaf of bread. This beer is about on a par with our best American beer. Instead of being a condensation of the nutriment contained in the grain in just so far as the liquid has undergone fermentation the nourishment has disappeared.

SUPPORT MEDICAL JOURNALS.—No man can fulfil the mission of a doctor unless he takes a good medical journal, and it is useless to cry poverty. The best investment a practitioner can make—one that insures him bread, meat and clothes—is not six, but fifty dollars' worth of good medical journals. If a man practises without this sort of communion with his brethren throughout the world he deserves to be poor. Surely the community in which he lives has a right to keep him so.—*Southern Journal Medical Science.*

CASES OF ORGANIC AND REFLEX PARALYSIS

TREATED BY ELECTRICITY.

By A. D. ROCKWELL, M.D.,
AND
GEO. M. BEARD, M.D.,
LECTURER ON NERVOUS DISEASES IN THE UNIVERSITY MEDICAL COLLEGE OF NEW YORK.

I.

In all the eras of medical history the treatment of the various forms of paralysis has been at once the opprobrium of science and the glory of empiricism. It is more eminently true of this disease than of almost any other with which humanity suffers, that while there are thousands of cases that defy the combined skill and experience of the faculty, there is yet no system of treatment so fantastic and absurd as not to be able in certain instances to perform absolute and apparently marvellous cures. There are few practitioners of large experience who have not known of cases of paralysis that have been to all human seeming permanently restored by practices that are abhorrent to science and reason, and that, too, at the hands of those who were as ignorant of the rationale of their own treatment as they were of the pathology of the disease. The causes of this discrepancy between the experience of science and charlatanism are not difficult of explanation.

1st. The obscure pathology of the different forms of paralysis.

The causation and nature of most of the diseases of the nervous system are even yet environed by darkness rather than by light, notwithstanding the faithful labors and brilliant discoveries of a host of able microscopists and pathologists. Prior to the last half century, all that was known to the profession of the pathology of paralytic affections was too vague and erroneous to be any guide either in diagnosis or therapeutics; and even in our day, in spite of the splendid researches of Romberg, Trousseau, Leroy d'Etiolles, Duchenne, Flourens, and Brown-Séquard, there are comparatively few among general practitioners who even attempt a systematic diagnosis between paralysis dependent on myelitis or other organic affections of the central nervous system, and those which are due to reflex action or to anæmia. This question of differential diagnosis that presents itself with every case of paraplegia, and is of such vital moment both for the prognosis and therapeutics, is either not raised at all or is answered without logical investigation or reflection. The direct and inevitable consequence of this uncertain pathology is primarily to make the treatment of paralysis almost entirely empirical, and ultimately to throw discredit on all measures of active interference, even in cases that proper investigation would show to be entirely curable.

Charlatans have busily occupied the field thus left open by the ignorance and discouragement of science, and have oftentimes surprised themselves and their patients by speedy and astonishing results.

2d. The helplessness and suffering caused by paralysis, and the lingering character of many of its phases, beget the desire and the opportunity on the part of the patient to test many styles of practice that are repugnant to sense or philosophy.

A patient who is stricken down in the prime of manhood by this mysterious chronic disorder, and who (as is so often the case) is counselled by his family physician to wait for nature and time, can hardly be censured for grasping at anything that offers the faintest hope of relief. We cannot wonder that such unfortunates are ready to *sow* beside all waters, even though they find neither satisfaction nor reward.

3d. The very recklessness, ignorance, and greediness of quacks have driven them to successful experiments that the conscientious and honorable would hardly dare attempt.

The spirit of Paracelsus and Sir John Long still lives, and amid a thousand blunderings it now and then stumbles on some path that leads to usefulness.

We would not be understood as underrating the systematic and patient investigations of a number of able minds, who for the past few years have labored specially in this department, and have contributed so much that is of practical service in the treatment of paralysis as well as in the study of its pathology. Chiefly among these recent observers is C. E. Brown-Séquard,* whose writings on diseases of the nervous system, for originality and boldness of thought, and for clearness and compactness of style, have few equals in scientific literature. But the conclusions at which he arrives, and which he so lucidly presents, are, to say the least, not indisputable. The variety of facts that he has collated are indeed of immense service to the student of diseases of the nervous system, as a guide by which to estimate observations that shall be made by future experimenters; though it may well be questioned whether all his brilliant generalizations will stand the test of the combined experience of the explorers that are to come.

His leading ideas in regard to the pathology of paraplegia, are clearly set forth in the following propositions:

1st. That there is a form of paralysis of the lower limbs, entirely distinct from all others, as proved by its mode of production, by morbid anatomy, by its symptoms, and by the influence of a certain mode of treatment; and that this form of paralysis fully deserves the name of reflex paraplegia.

2d. That the reflex paraplegia may be caused by the most various irritations of the skin, the mucous and serous membranes, the abdominal or thoracic viscera, as well as of the genital organs, or the trunk of the spinal nerves.

3d. That most cases of paraplegia can be placed in two groups, entirely different one from the other, according to the existence or the absence of symptoms of irritation of the motor, sensitive, and vaso-motor nerve fibres.

4th. That most of the therapeutical means to be employed in paraplegia are also to be grouped in two categories, one of which is fitted to those cases in which there are symptoms of irritation, and the other to those cases in which these symptoms do not exist.†

The "therapeutical means" referred to in the last proposition are as follows:

In reflex paralysis.—1st. Means of diminishing the external irritation that causes the paraplegia—viz., local applications of belladonna, or of opium, or of both combined. 2d. Means of improving the nutrition of the spinal cord—viz., strychnine, sulphuret of potash, sleeping on the back with the head and legs elevated, applications of cold and heat to the spine, revulsives, "galvanism." 3d. Means of preventing the ill effects of rest in the paralyzed nerves and muscles—viz., "galvanism" and shampooing.

Paralysis due to myelitis, or to some congestive or in-

* Course of Lectures on the Physiology and Pathology of the Central Nervous System.

† Lectures on Paralysis of Lower Extremities, p. 118.

flammatory condition of the spinal cord or its membranes. —1st. Means for diminishing the congestion of the spinal cord—viz., sleeping with the arms and legs on a lower level than the spine, hot and cold applications, dry cupping, revulsives, belladonna and ergot of rye. 2d. Means to prevent the formation of sloughs, or to cure them when formed, and to prevent other alterations of nutrition in the paralyzed parts—viz., pounded ice and poultices, shampooing, warm foot-baths, the flesh-brush and galvanism, remedies for any nephritis or cystitis that may occur, laxatives for the bowels. 3d. Tonics—cod-liver oil, iron, ale, and nutritious food.*

We have been thus minute in presenting the teachings of Brown-Séquard for the following reasons:

1st. Because, whatever exceptions may be taken to his generalizations, he is indisputably and justly regarded as one of our highest authorities on the diseases of which he treats. The relative position that has been thus accorded to him, in this country at least, has been mainly due to the fact that his opinions on these somewhat abstruse subjects, whether firmly grounded or not, are stated with a clearness, a positiveness, and an authority that can but command attention. 2d. Because, in our view (although, as will be explained further on, we are not prepared to endorse all of his statements in regard to reflex paralysis), his system of therapeutics for *all* relievable paralytic affections, is at once catholic, scientific, and comprehensive, since it is based on a differential pathological diagnosis, and practically includes the best results of daring quackery—the movement cure, rubbing, and galvanism—as well as the judicious administration of remedies. 3d. Because, as we shall endeavor to show by theory, by general experience, and more especially by detailed exhibition of cases, these indications for the treatment of the nervous forms of curable paralysis are more fully met by general electrization † with the faradaic current in conjunction with localized electrization—either with the faradaic, or, in some cases, with the galvanic current—than by any other one system that has yet been proposed.

In regard to general electrization with the faradaic current, we speak only from our own experiments on ourselves and on the living subject, and from a considerable experience with a variety of diseases, since we were the first to call the attention of the profession to this method of treatment.

So far as merely localized electrization with the faradaic or galvanic current is concerned, our experience was in the main anticipated, and has been corroborated by Duchenne, Tripier, and Seiler in France; by Profs. Remak and Ziemssen, and by Drs. Rosenthal, Meyer, Benedict, Erdman, and Bastings in Germany; by Dr. Althaus of London, and by Drs. Garratt, Weir, Mitchell, and W. A. Hammond of our own country. We claim that *general electrization with the faradaic current* is a *general tonic* and corrective of very great efficacy, and that as such it fulfils the following specific indications:

1st. To strengthen and soothe irritable and painful nerves or organs.

2d. To prevent atrophy and fatty degeneration that may result from too long disuse of paralyzed nerves and muscles.

3d. To equalize the circulation; to bring the blood to cold parts, and *vice versa*, to diminish congestion.

4th. To prevent the formation of ulcers in paralyzed parts, and to hasten their cure when formed.

5th. To produce general tonic effects in the whole system, by correcting the deranged organs of assimilation, and stimulating all the various processes of waste and repair. These constitutional tonic effects of general electrization are demonstrated in the same manner, as from the internal administration of tonics—travelling, sea-bathing, riding—viz., by increase of appetite, making the sleep more refreshing, relieving nervous and inflammatory pains, regulating the bowels, improving the circulation, the color of the cheeks, the muscular development, and the *tout ensemble* of the individual.

For proof of these statements we refer to our treatise already published, and to the details of cases that are to accompany these articles. The power of electrization (whether with the galvanic or faradaic current) to soothe irritated and painful nerves or organs, is so very easy of demonstration, that we wonder that it is not more generally appreciated by the profession. Acute neuralgias are often instantaneously relieved by the application of a fine current, directly over and along the painful nerves. For aching eyes and irritable throats and urethras, no anodyne is at once so efficacious and so harmless. The harmlessness of electrization, used in this way, gives it in many cases a manifest advantage over hypodermic injections, or the internal use of opiates.

Were electrization only useful in neuralgia, it would deserve far more attention from men of science than it has yet received.

It will be observed that the effects here claimed for electrization are substantially those that, according to the theories of Brown-Séquard, are desired in the various forms of paralysis. That the most important indication of all, viz., the equalization of the circulation, is excellently met by electrization, we have repeatedly and daily demonstrated in our own practice and on our own persons, and in the presence of various members of the medical profession.

If the bulb of a thermometer be applied to a limb, in which the circulation is normal, or is deficient, just before and just after electrization, it will be found that there is oftentimes a very perceptible rise in the temperature; and *vice versa*, electrization of inflamed joints or other parts, reduces the temperature, dissipates the redness, relieves the pain, and diminishes the swelling, thus ameliorating all the symptoms of inflammation.

This last effect is best secured by a very fine induced current, gently applied with the moistened hand.

Although electrization in active inflammation is contrary to most of the teachings of the past, yet this is only another evidence of the irresistible tendency of the human mind to accept the dictate of leadership without doubt or question. The antiphlogistic effects of general electrization are much more decided than when the applications are merely local, for the reason that, by the former method, the great sympathetic and the entire system are affected, and then react on the diseased part. We are continually demonstrating the antiphlogistic effects of electrization in inflammations of the conjunctiva, the nasal passages, pharynx, larynx, bronchi, the urethra (the acute and passive stages of gonorrhœa), and in inflamed joints.

Now, although the bone is comparatively a poor conductor, yet the articulations of the spinal column will not wholly prevent the influence of the electric current; but the cord is, probably, chiefly affected by the impression it receives from the electrized periphery.

If injurious irritation of sensitive nerves operate directly on the central nervous system, as rightly claimed by Brown-Séquard, then certainly there is a fair probability that tonic and corrective impressions of the periphery may operate favorably upon the same system. This question will be discussed more in detail further on.

In this connection it may be well to state that all

* Lectures on Paralysis of Lower Extremities, *passim*.

† For explanation of this and other terms employed in electro-therapeutics, the reader is referred to our recently published treatise on the Medical Use of Electricity.

the results that we have here or elsewhere claimed for general electrization, can be secured in all their fulness and variety by any or all who will bring to the investigation the requisite energy, enthusiasm, patience, and earnest love of truth. It is, perhaps, too much to be expected that our older practitioners will find it possible, amid their heavy responsibilities, to pursue a department that demands so much time and special experience as the scientific study of electro-therapeutics; but for younger men, who have health and opportunity, the field thus opened for the energetic and persevering is too rich in promise of usefulness to be any longer passed by. Since we first formally called the attention of the profession to the tonic effects of general electrization with the faradaic current, we have been gratified to learn that others in different parts of the country have commenced to experiment with this method of treatment, and some of these have already met with sufficient success to more than corroborate all that has been claimed for it.

914 BROADWAY.

ON THE PREVENTION AND TREATMENT OF SCARLATINA.

BY N. L. NORTH, M.D.,

BROOKLYN, N. Y.

I WAS greatly pleased on reading in the last number of the *N. Y. Medical Journal* an article by Dr. C. C. Lee, "On the Internal Use of Chlorine Water in Anginose Scarlatina," as it so exactly accords with my own experience of the last few years, as also with the recorded experience of so many English physicians for the past five or ten years, as may be seen by looking over the files of Braithwaite for the time. Mr. E. J. Blyth, in 1863, and again in 1864, particularly calls the attention of the profession to this treatment in the following language: "Let me urge my medical brethren to give a full and fair trial to my remedy, relying implicitly on it. . . . . I see no reason why every one using this remedy fully, should not be blessed with the same success that I have been, during many years that I have used this specific in an active and extensive practice."

The formula given by Mr. Blyth is (except that there are ten instead of eight grs. of chlorate of potash) the same as that given by Dr. Lee, and the same also as may be found in "Watson's Practice of Physic." In fact the remedy is not a new one, or not an uncommon one, and yet I believe it might with great good effect be more *widely* known and more *generally* used. Any practitioner who will try the remedy need not long be in doubt as to its great value in anginose scarlatina. I myself had the honor, in August or September, 1864, of reading a paper on scarlatina before the "Medical Association of the E. D. of Brooklyn," wherein I particularly urged upon my medical brethren the use of the hyposulphite of soda as a prophylactic, and as a general remedy in scarlatina, and the "*chlorine mixture*" in the anginose or diphtheritic variety. I also give it and urge its use in pure diphtheria as a remedy of far greater power than any other I have ever used. I speak of the remedy as a "chlorine mixture," for it is evidently *not* a simple "chlorine water," but a mixture of pure chlorine with the chloric and hydrochloric acids, and is to most people pleasant to the taste, while the "chlorine water" of the Pharmacopœia is *very* disagreeable to the taste, and, according to my experience, of far less value in scarlatina anginosa or diphtheria, than the chlorine mixture which I have prepared as follows:

Put ten grains of the chlorate of potash, finely levigated, in a pint bottle; cork it; add one drachm of hydrochloric acid; in a minute or so add an ounce of water, and shake; to dissolve the vapor, let it stand a short time; then add more and more water at intervals until the bottle is filled.

I direct my apothecaries to be in *no haste* in the preparation of the mixture, but to prepare it beforehand, and add the water ounce by ounce, and allow sufficient time between each addition for the absorption of the vapor or gases. I find physicians are in the habit of using chlorate of potash and hydrochloric acid with water—writing extemporaneous prescriptions therefor—in very much larger quantities of the acid and potas. chlor., yet with nothing like the effect; and I have again and again surprised them with the strength and efficiency of my chlorine mixture made after the formula of Dr. Blyth above given. I find it again very necessary to *know* my apothecary; as, with our *model* arrangement of *learned* apothecaries, I find it very difficult to "*beat it into the head*" of more than about one in fifty that the *manner* of compounding medicines is, many times, of as much importance as the *matter* of which they are compounded.

As to the dose of the chlorine mixture, I give, according to the age and condition of the patient, from a teaspoonful to two tablespoonfuls, diluted with pure water, at intervals of from one to eight hours. Much larger doses may, and have been given, but I find these doses large enough, and much prefer giving small quantities frequently, to larger doses at longer intervals; as it seems to me its action is more antiseptic and disinfectant than otherwise, and the more *continuous* its application to the seat of the disease, the better for the patient.

The *N. Y. Medical Journal* published a short communication from myself, in March, 1866, in which I advocated the use as prophylactic for, as well as a remedy in, scarlet fever, of hyposulphite of soda, and the chlorine mixture in the anginose variety. Dr Blyth recommends the chlorine mixture alone for the same purpose. I wish here to add to what I said in the communication mentioned, that I still believe the hyposulphite of soda to be a prophylactic of more power than anything ever yet used, and that its apparent failure is explainable in the fact that the profession is looking for some specific (as vaccination for small-pox) for scarlatina, and have given this medicine, as they have others, with that idea uppermost. Now if the ground be taken that the medicine acts as an antiseptic and disinfectant, we shall not give it for a few days, and think we have obtained its preventive effect upon the system, but we shall administer it to the well children as a prophylactic during the *whole time* of their exposure.

In March, 1867, the Metropolitan Board of Health (so the newspapers informed us) passed a resolution including *scarlet-fever*, measles, diphtheria, etc., in their category of "contagious diseases." I did hope at the time that some recommendation might emanate from, or that some order would be issued by the Honorable Board, requiring the systematic use of disinfectants and prophylactics in these diseases, if any could be sufficiently relied upon to warrant a trial; but I was doomed to disappointment, as I heard nothing more of the resolution until *June* (about the time it usually takes, by the way, for a resolution or order of the Metropolitan Board of Health to be promulgated, or carried into effect in this far-off region of the Eastern District of Brooklyn), when I was officially informed that said resolution had been passed. That official document also contained the following: "Physicians, when reporting cases of contagious diseases, are requested to state whether any action on the part of the Board of Health is needed in consequence

of the condition or surroundings of the patient." I, for one, did not know what they meant, as they had not stated what action they proposed to take in such cases; and I was glad to find in the report of the proceedings of the "East River Medical Association" that that society had appointed a committee to inquire of the Board of Health what they did mean, or what they proposed to do. Yet I was again disappointed in the answer; as I had hoped, as I before stated, that some definite action would be taken which would result in some useful statistics. I desire to add one word in regard to the use of the chlorine mixture and the hyposulphite of soda, particularly in scarlatina and diphtheria. It seems to me these medicines should not be depended upon to the *exclusion* of tonics, iron, etc.; for if they act only as antiseptic, and if they are curative only through removing or destroying the poison which is the cause of, and which is generated by the disease, and if either or both to any extent act as a prophylactic, by destroying the communicated poison previous to its development of the disease in the exposed person, then of course in actual disease the necessity of toning up the system and striving to repair the damage done, should by no means be lost sight of. I have, for instance, given the chlorine mixture in severe cases of diphtheria, and destroyed the whole of a bad membrane in from twenty-four to forty-eight hours, and in twelve hours more have found my patient as bad as at the first, and of course thought it necessary to redouble my efforts to cure. I have again, in just as severe cases, given the mixture, and immediately followed by, or alternated with, the tr. ferri sesquichloridi, and other tonics, and have had the satisfaction, not only of seeing the fauces clear up and resume the healthy state, but find the whole system of my patient rallying to a normal state, and thus preventing a return of the diseased condition.

BROOKLYN, N. Y., September, 17, 1867.

Original Lectures.

ON YELLOW FEVER.

DELIVERED SEPT. 23, 1867, AT BELLEVUE HOSPITAL, N. Y.

BY WARREN STONE, M.D.,

PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF LOUISIANA, ETC.

YELLOW FEVER is a disease which everybody seems to understand, yet few agree upon its exact nature and character. It is a disease simply peculiar to the South, to certain warm regions. The exact laws that govern it we have not been able to define. Many observations have been made as to the temperature necessary to the existence of this disease, and certain theories have been in favor for a length of time; but all arbitrary rules have been set aside, examples having occurred to falsify them. Yellow fever is simply and purely a disease that can exist only in warm climates. It is induced by a peculiar poison, totally intangible, and distinct from any of the known causes of disease. There is no combination of filth—no combination of circumstances, calculated to deteriorate health and excite typhus or typhoid, or fevers of a low grade, that have anything to do with the generation of this disease. This is a remarkable fact, not generally understood; the filth of cities does not generate yellow fever, though it has the same influence upon it as upon other diseases, by impairing the vigor of the system, and rendering it more susceptible to morbid agents—but that is all. Sanitary measures are important, and I would not say anything to deter people from insisting on cleanliness in cities; but some Federal officers took credit to themselves for keeping yellow fever out of New Orleans during its occupation. It is a notorious fact that the city was not cleaner than usual during that time, but the conditions were more favorable; the weather was cooler and pleasanter, and there was less rain than usual. The principal thoroughfares may have been a little more clean, but the suburbs and surroundings were as fruitful sources of disease as ever. There was no material difference. We had had six successive years of exemption in other times, and that when there was no quarantine whatever. The fever fixes upon the healthiest locations with as much virulence as upon the low regions. Back on the Magnolia Ridges, looked upon as the most healthful region on the earth, it has prevailed with great severity. Indeed, it is generally more destructive in the country, when it occurs there, than in cities. But the character of the disease has been sufficiently written upon, and I will confine myself to a few points in dispute.

I. As to its etiology. There is great dispute upon a subject one would suppose might be reduced to a matter of fact, viz.: whether it is imported or of local origin. The epidemic influence is certainly not imported in ships; it is wafted through the atmosphere and takes a wide range, confining itself to no little narrow place. It seems as if it came in one grand wave, and went round in cycles. We have exemption for several years. It generally appears first on the islands and in the ports of the Gulf. If it is late in the season we do not get it in New Orleans that year, but next year that atmosphere or influence reaches us with a good deal of certainty. In 1851 it commenced in Brazil and on the Rio, and progressed regularly northward, taking the West India islands in 1852, and reaching New Orleans in 1853, when it was of the same character, virulence, and severity that characterized it in the places it had previously visited. It ran from one city to another, and along the Atlantic ports for several years. In 1855 it reached Memphis, and many of the interior towns suffered severely. This year its history is worth noticing. We had had in New Orleans sporadic cases, with evidently no intensity of the poison. This was early in June. When an epidemic has visited New Orleans it has generally appeared at two points, above and below the city, where shipping mostly lay, and where there was the greatest congregation of subjects calculated to take the disease, owing to bad living and want of ventilation and proper dormitories. It usually starts from the river and goes backward, attacking all who are in the vicinity. This year it did not begin thus; but cases occurred here and there irregularly in all sections of the city, not being intense enough anywhere to affect all who were exposed. At the same time, the weather was such as favors the development of yellow fever—frequent rains followed by a hot sun. These rains frequently occurred two or three times a day—not sweeping rains, but enough to keep everything damp, so that one's boots became mouldy while he was asleep at night. This weather lasted the whole of June and July, yet the fever did not increase at all, and everybody felt, therefore, that there would be no epidemic; for I should remark another thing: when yellow fever once commences as an epidemic, it goes on by a regular grade,—one case to-day, two to-morrow, four the next day, and so on until it reaches its height, and then it declines pretty much in the same ratio. This year, up to the time I am speaking of, there had been nothing of the kind; but after this state of things had continued some time, yellow fever appeared on the Gulf coast, coming from the direction of Mexico. The disease was evi-

dently of a more severe character, and I remarked to some one that there was an epidemic influence which I was pretty sure would reach us. The fever seized on Indianola, Texas, and, taking other towns on its way, broke out at length in great severity in New Iberia, a village about a hundred miles west of New Orleans. It was the more severe there because there had been an accession to the population, in consequence of recent drowning out by overflows.

Just a day or two before I came away the fever had reached New Orleans; and though the weather was unfavorable to the disease, it nevertheless increased steadily from nine cases a week to as many in a single day. It is fair, therefore, to infer that the epidemic which started in Texas, on the Gulf coast, swept on and reached us, and really was the epidemic we are now suffering from. This is the general character of the disease, though occasionally it will fix upon a place, run its course, and not extend further; but that is not usual. It seems to be some influence like influenza, which sweeps along, affecting almost every one within its reach.

II. The question of the contagiousness of yellow fever is an important one, and ought to be settled. It was entirely conceded that it was non-contagious until 1853, when the disease swept over the land with such violence that everybody thought they could see how it was carried. Medical men differ upon the subject; but it is important to decide the question, for many reasons, especially with regard to quarantine, and to the suffering persons themselves. Under the view that it is contagious, those who are seized are liable to be neglected by all but their nearest relatives, and even they attend them with reluctance. I am perfectly convinced, beyond all doubt or hesitation, that personally it is not contagious. I *know* that it is not. Whatever is contagious ought to be tangible; there ought not to be any dispute about it. A disease that is contagious once is always contagious. Yellow fever is the same thing in every place where it occurs; it is a specific disease, and the same subject has it but once, and does not lose his acclimation, no matter where he goes or how long he remains away; but there are some traditional points of belief on this subject, and the human understanding is very hard to convince in such cases. We have, however, abundant opportunities of proving that persons never lose their acclimation, and never have the disease but once. There are of course occasional exceptions to this rule, as to all others. Small-pox is said to occur a second time, though I have never seen it myself. If yellow fever is contagious, as contagionists contend, it should be extremely so, so that there could be no doubt of it. They cite far-fetched instances in proof of its contagiousness, but isolated cases prove nothing. I have witnessed the disease on a large scale, and could not have failed to observe it. I do not claim to have been a close observer; but I have been an honest one, and have endeavored to avoid theorizing. It is too common to form an opinion or theory, and then hunt for facts to verify it. I endeavored to have no opinion beyond what was to be inferred from the facts before me. The first opportunities I had were in the Charity Hospital of New Orleans, in my first season there, in 1833. I had arrived after being shipwrecked, and having lost almost everything. I found it difficult to get any place. I was merely assistant in the Charity Hospital. The epidemic was very severe for the number of the population. The fever commenced in the usual manner, toward the river, and spread backward gradually, street by street. The Charity Hospital was then back on the confines of the swamp. You could shoot duck from the walls. The fever did not really prevail there. The poor inhabitants, living in little cheap houses in the vicinity of the hospital, escaped the yellow fever, and none except the male portion, who worked in other parts of the city, were affected by the disease. This I was aware of from having attended them personally. It would appear that the hospital itself was not the seat of this poisonous influence. The hospital, therefore, and those who stayed in the hospital, were more exempt from fever than those outside. The hospital became crowded, because there were so many strangers in the city who had no friends, that the directors gave orders to receive all who came. The accommodation was inadequate. The servants were sick, and none could be hired. The consequence was that the hospital became filthy; the passages were often filled up with bedsacks covered with excrement, black vomit, etc. So much of this filth accumulated that it generated a low house fever of a peculiar character, something like jail fever, the patient having a dry black tongue, with sordes on the teeth, and falling into a dull lethargic condition, from which, however, they recovered rapidly under the use of stimulants. People, therefore, actually became sick from the filth of yellow fever, and escaped yellow fever itself, simply because the hospital was situated at a point where the atmospheric influence did not prevail. I was there all the time, and did not take the fever until the 28th September. I was with the fever; I dissected everything (I handled the corpses, and had lifted out ten bodies the day I was taken) in order to discover if possible some facts that would suggest proper remedies, for the disease was treated abdominably. In 1853 three hundred cases of yellow fever were treated, in the Charity Hospital and in my infirmary back of the city, by some ten or twelve sisters of charity, all of whom were unacclimated. Yet these sisters were the last persons in the house to take the fever, simply because the atmospheric influence did not prevail there. In 1847 I had two young men as assistant house surgeons in the hospital with yellow fever, and they were the two last cases that took the disease, though they had been over it all the time. At the time they took it there were no other cases in the hospital. In 1853 and 1854 there was one nurse in the Charity Hospital who lived there during the whole time, and did not go out. In the winter of 1854 he left the hospital for other purposes; and in 1855 he was one of the first cases brought in with yellow fever, and died with black vomit. That is only an isolated case, but I merely mention it. In 1859 a ship came in from a German port with three hundred emigrants on board, of the better class, and yellow fever among them. They had sailed on the south side of Cuba and got the disease away out at sea, where it would be difficult to quarantine it. They had been becalmed in that hot region. Some forty of these subjects were brought to Charity Hospital and placed indiscriminately along with numbers of other unacclimated persons. The disease ran its course, and a large number of the forty died, but not a solitary case took it in the house. These are instances which occur on a large scale. Nobody will pretend to say you can place forty cases of the misnamed Irish typhus, or ship fever, among other patients without some of the others taking it, though that disease requires some little exposure. They would get it with us, but the disease would not stay with us; it soon ran out, and was not disposed to spread as it does in northern cities. But we have instances continually in New Orleans to prove the non-contagiousness of yellow fever. In the beginning of epidemics, when the disease is located in the lower part of the city, cases occur of men taking the fever, and being brought

away and treated in healthy parts of the city. In such cases nobody takes the disease from these persons. In 1856 and 1857 yellow fever occurred in the city, and was strictly confined to about six squares; and though the poison was evidently potent, there were no cases outside. They were very anxious to prove that it was imported, but these cases had had no connection whatever with anything that came into the port. It originated there. Forty cases, I think, were brought to Charity Hospital, and I traced them all to this region. It was my habit to find out whence each case came, and all these cases could be traced directly to this region, limited to six squares. Nobody else took it from the cases brought us, nor did any new points of infection occur. But it is strange how easily the human mind is convinced upon a subject when it wants to be convinced. After the epidemic of 1853 I went into the country, and thought I would make inquiries from the common people who had no prejudices. I found them about equally divided, each having made up his opinion from what he had seen. One had had a case brought into his house, and nobody took the fever from it; but he had seen cases where overseers had gone back of the plantations to escape it, and had there taken it. There was one favorite instance cited among them, of a family living in the "Piney Woods," of six men, the father and five sons. One got the fever, and all took it from him, and all died. I did not take any pains to argue with them, for you will find the most difficult people to argue with are those who do not know anything about the subject. I finally asked an intelligent man, "Pray, where did the first one get it?" Said he: "The first one had gone to the banks of the river, and was standing on the high bluff when a steamboat, having yellow fever on board, passed up, and he took it." Now, I visited the place, and the spot where he stood was three-quarters of a mile from where the steamboat passed him in going up; so if he took it in that way, it would argue contagion beyond all doubt. But many persons make up their minds from instances just as far-fetched as this. I mention these circumstances, which have convinced me that yellow fever is not personally contagious. How far its atmosphere may go, or how much atmosphere bottled up or carried in a ship may contain poison enough to give it to a person who may be so unlucky as to breathe it, I cannot say. I have thought a ship might become charged, and, with the hatches closed, might contain enough poison to communicate it by inhalation. This is not an unreasonable supposition, but I do know that the fever patients themselves, and the filth that accumulates around them, do not generate the disease. So far as the theory of its being carried by ships is concerned, it would be well to inquire into the condition of ships coming from infected ports; but in case of its being communicated that way, it is certain that it would go no further than the individuals who went on board that ship and breathed that atmosphere.

III. The disease itself varies in the manner of its attack. The most favorable attacks are those where it is ushered in at once with marked and prominent symptoms; where the patient is taken with rigor (not a violent chill), followed immediately by pains in the limbs, back and head, with reaction, heat of the skin, and fever. But in a great many of the cases the attack is insidious, accompanied by a kind of energy which enables the patient to be up, though he has a little rigor and aching in the limbs. He keeps about a day or two; but the disease is making its progress in the blood all the time, so that when a physician comes the patient says he has been sick two hours, when he has really been sick two days. While the patient is moving about, the poison causes more fearful ravages upon the system than when he is quiet; and that is why those cases are more favorable where the disease is ushered in briskly at once. The physician is more likely to see them at the beginning, and the patient is more likely to adopt proper measures. That is the reason the disease is so troublesome now. A large proportion of the cases occur among strangers, who have nobody to coerce or take care of them, or direct them. Many of the cases, as virulent as they would appear to you, are mild, though the mild cases are just as sure to kill as any others; and almost all will prove fatal unless the patient is managed properly and kept quiet. Take a plain common case—that is ushered in at once with rigor, and pains in back, head, and limbs. There is sometimes also capillary engorgement, particularly noticeable in the eye, though it is not that conjunctival engorgement frequently seen, but a redness of the vessels of the eye which is not seen in any other fever; and in the same proportion will you also see a peculiar redness of the skin. That, however, cannot be said to be characteristic; but you often see it. If the patient is placed in bed and under favorable circumstances, he is disposed to go into a sweat, as after a common chill of intermittent. This affords some relief, but not much. The pains continue, and if the case is a favorable one, the sweating will go on until that and the heat subside together, provided the patient is kept perfectly quiet. Then, if he is nourished, he will rally and suffer no more than the one paroxysm. Three days is the most common period. In the course of the third day the fever leaves, and the patient is then in a favorable condition. It is then essential to nourish him. He ought not even to raise his head from the pillow until his blood has been renewed. The effect of this poison, whatever it is, is such upon the blood that it almost destroys it; and if the patient is allowed to get up, a faintness comes over him, perhaps accompanied by nausea, and sometimes the whole process of the disease is renewed. With faintness, and a loathing for food, the patient generally dies with great certainty, when he would be perfectly safe if kept quiet and nourished. This is the course of favorable cases.

IV. The treatment of such cases is simple. With regard to purgatives, they do not want them. There is too much disposition to purge patients. If the patient has been eating recently, and has ingesta on the stomach, it may be desirable to evacuate it from fear of fermentation, and consequent irritation. A little oil will act easily, and be effective, if taken four or five hours after meals. If the bowels are constipated, a simple injection, to evacuate the lower bowel, is all that can be useful. Then let the patient alone, and never let him get out of bed until he has been thoroughly nourished. If I see them in the beginning of a case that is ushered in suddenly, as soon as there is any perspiration I give a full dose of quinine. The effect is remarkable. There is no doubt about its value at this time. It quiets all those pains as completely as in a case of neuralgia; it checks the rigor and promotes perspiration, and if you manage them carefully they will go on sweating, and there will be no return of the fever. I used sometimes to give a smaller dose of quinine next day. I do nothing else, but regulate the drinks. There is nothing more to be done. There is no pathology visible; there is no organic disease; nothing to be found by the dissecting-knife. There is simply this condition of blood, which is shown later by discoloration of the skin. The pains in the head and back induce many to make ice applications. I do not think they do any good, but on the contrary a good deal of harm. If you once make the application, and it is left off for a

moment, reaction comes on, and the pain is intense. If you do not put ice on at all, the patients complain very little. My patients very seldom complain of pain. Once having applied ice, you must keep it constantly there during the whole course of the disease, and even afterward, and I believe they suffer a great deal less if you do not use it at all. Cups have been very much used at times. Some men who adopted this plan of treatment made quite a handsome fortune during the yellow fever season. Everybody had to be cupped, on the stomach, back, and behind the mastoid processes. There is no advantage in losing blood unless the patient is plethoric; then he may have a little surplus blood taken, perhaps with advantage. As for applications of mustard, I find the less the patient is disturbed the better; but sometimes a sinapism over the back relieves them in a remarkable degree. You can reapply it as often as you please. The same application to the back of the neck will relieve the pain there, and is almost always more or less valuable. The matter of nausea is of the first importance. Until they are nourished they cannot get up with safety, even though they have had a very light attack. I give any nourishing drink they can take often during the disease; and they will bear stimulants in almost any stage, if they crave them. There is a peculiarity in the stomach of the yellow fever patient: he will retain anything he likes, and reject almost anything that is unpleasant. I would not inculcate the idea that they need stimulants during the disease, but it may be given while the fever is on; and you will find the local symptoms are not aggravated by stimulants when the general condition requires them. Those who have been accustomed to stimulants will sometimes take them while they have fever. I usually allow just what they crave; and they will take brandy when they have fever, and the skin will become moist under it, and the pulse slower; though I should remark that the pulse is not generally very frequent, and seems to have a good deal of force. There is generally some uniformity of the taste in craving stimulants. Some years they generally crave malt liquor, as good Scotch ale; other years champagne, and other seasons brandy; and it can always be administered, even during fever, if there is a sinking condition with disposition to sigh. After the fever has subsided, you can give them malt liquor. I prefer it if the patient likes it. Then they will very soon rally, and any solid animal food or other proper nourishment may be given. If the patient, from any cause, is not inclined to take nourishment, it is always advisable to give it by injection. The rectum will absorb it. I have fed cases in this way, and they have rallied. Any way to get nutriment into the system. If you do not administer nourishment in time, the patient will loath it, and you will then find it difficult to nourish him it all. It does not take much to answer the purpose; convalescence is rapid, and they will soon get up and go about their business. This is only in the favorable cases. In patients who knock about and are imprudent, the fever will run five or six days, the skin becomes dry and hot, and it is useless to attempt to promote perspiration. I would remark that the sweating is often overdone. Patients are kept sweating under blankets in hot weather until it oppresses them. You may carry a proper course of treatment to excess. The idea is to keep the patient covered and perspiring without carrying it to excess; but if you pass this stage, and the hot stage comes on, this will run five days; the patient will feel perfectly well, and then there will come on a relapse, and black vomit follows. Some use cold baths; but the less the patient is disturbed the better, so I prefer sponging quietly. There is a singular sense of exhaustion, and I always consult the patients with regard to the use of water. The patient will generally convalesce in the same manner when the disease terminates on the third day; but you have to watch carefully, for you can sometimes anticipate symptoms, and give medicine for what is going to be.

You will perhaps observe the patient becoming restless, and he will tell you he has a little burning in his stomach, and then you know that he is progressing toward black vomit. Muriatic acid is about to be formed in the stomach, and you may anticipate it. The best remedy I have found to be small quantities of bicarbonate of soda and morphia—about one-fourth of a grain of the latter in a four-ounce mixture with a little soda, of which mixture teaspoonful doses may be given. It is remarkable how susceptible they are to opium, and by the soda the acid is neutralized. In the way of nutriment, beef-tea, either by the stomach or by injection, is of great value. If you can wear the patient through this stage he will get well, while he would die with perfect certainty but for these little things. It is the judicious use of little things that saves him. People generally think it is a mighty disease, and wants mighty medicines—great things to tear them all to pieces. When I first went to New Orleans, sixty grains of calomel was the ordinary dose; and they often liked to give more. Some used to carry it in their pockets, and having given as much as they dared, they colored it with charcoal; but it was calomel to the end, and it was remarkable that some of the patients got well, too! Another feature of the disease is, that when it is ushered in with rigor the patient is a little delirious. That is not significant in the fever, but shows a degree of enervation if it comes on later. It is one of the conditions you should anticipate. The patient may discover a disposition to this aberration, which you may treat by a simple anodyne and stimulant, and thus prevent subsequent delirium. When it once sets in it is like mania à potu, and is unmanageable; the patient exhausts himself if you do not give anything, and if you do, he goes into coma and dies; so you must observe the symptoms in season. It is that nice observation which enables one to take advantage of little things and prevent serious mischief. I look upon a patient with yellow fever as a perfectly irresponsible being; he talks to you reasonably, but he is a crazy man; he is completely perverted; he will get up; he will say he has no fever; he will talk quite rationally, except that he is a little more susceptible, and disposed to be argumentative, and it is difficult to make him obey. It is for that reason the disease is so destructive now, and always among strangers. It is strange what a difference there is in favor of a patient in a family where there is a sensible matron to take care of him. Ten such cases will give less trouble than one elsewhere. She sees the beginning of the disease, and prevents patients from going out till your next visit, when she tells you quietly there is another case. Yellow fever patients are apt to labor under a misapprehension as to themselves. There is a sort of exhilaration that gives them a don't-care feeling; they are sure to think they have some important business to attend to and must go out, but they cannot tell you what it is if you ask them. That is one cause of the fatality of the disease. It works upon the system with much more severity while the patient is knocking about. I have met them walking on the sunny side of the street buttoned up to keep warm. They perhaps get chilled, and are picked up in a stupor. They cannot be advised or restrained. This is true of those who have been staying there on purpose to become acclimated. They feel so well after the fever subsides, that they cannot be induced to stay in bed. I

have known the fever, under quinine, to disappear in twenty-four hours. But if they get up, having taken, perhaps, fifteen or twenty grains of quinine, they cannot walk across the floor; but will faint and fall, if the fever has gone. Yet you will find great difficulty in keeping such a one in bed. Of course, those left to themselves will get up, have a relapse, and die in the end.

There is little more to be said in regard to treatment. Purging is to be avoided, though it is remarkable how much violent treatment patients will bear. If they have a fair chance otherwise, two out of three will get well under very harsh treatment. I took occasion when I had command of a hospital to make a comparison. We had about six visiting physicians in the house, and all had some favorite mode of treatment—all more or less perturbating and active. Each one boasted of his success. I, having charge, ordered that patients should be sent in rotation with the utmost strictness, so that each physician should have about an equal number of good and bad cases. I happened to have four wards myself, and at the end of the month I found by the report that the several physicians had results just about the same, once in a while a case or two being in favor of one or another; whatever perturbating treatment was used, it made no difference, but there was a difference of ten per cent. in favor of letting them alone, and simply managing them on the principles I have mentioned to you. Any one would like, in a case of life and death, to have the ten per cent. advantage. I should mention that cases were sent to my ward the same as to the others, and I had no object but to get at the facts. There is a curious disposition in people to think they are getting the fever when they are not, and when they do get it they will not believe it, and will commit imprudences that favor the progress of the poison. I should say further of the use of quinine, that I have never known any one to use it as it should be used. I never give it but at the outset of the disease, just as the rigor has passed off, and the fact that it relieves pain shows it to be useful. It promotes perspiration, and prolongs the sweating stage. A larger number of cases under quinine will terminate the hot and sweating stages together, so that you resolve it into one paroxysm, and that a short one, and less likely to return. Without quinine the fever is more likely to return and render the case dangerous.

I cannot insist too much, in conclusion, on the total irresponsibility of the patient, and the great importance of keeping him quiet by gentle means, and without rendering him impatient. Force would only do mischief. I recollect the captain of a ship (and they are generally a little imperious), who was my patient, and was doing wonderfully well one night when I left him, but who, on my visit next day, had defied the nurse and driven her out of the room. He was then beginning to gulp, and was going rapidly toward black vomit. I took him by the shoulder, laid him down, and told him seriously I would cut his throat if he turned right or left before I returned. He was alarmed, obeyed me, and got well, and used afterward to laugh over it, saying he was firmly impressed with the idea that I would really do as I threatened if he disobeyed. This shows the peculiar condition of the mind, for he could converse rationally at the time.

I will only add that nothing is to be gained by depletion, and that I have had cases where the bowels were unmoved for six days, and that yet did well. It is better to avoid all causes of exhaustion, even that attendant on the use of the bedpan.

VELPEAU'S LAST WORDS: *Il faut toujours travailler, mes amis.*

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, OCTOBER 2, 1867.

DR. HENRY D. BULKLEY, VICE-PRESIDENT, in the Chair.

TSA-TSIN, OR THE RHYNCOSA EXCAVATA, AS AN EMMENAGOGUE.

DR. PRINCE presented a very interesting report concerning the above agent, in the course of which he recited fifty-five cases in which the drug had been exhibited. Twenty-six of these occurred in his own practice. He proved that this Chinese remedy had attracted the attention of some of the profession in England some sixteen years ago, but since then, strangely enough, had fallen into disuse, so that now it was generally regarded as a discovery. It had also been employed by German physicians. The Doctor exhibited a specimen of the article furnished by its importer, Mr. Albert Dung; this was in a coarse-grained powder of an olive-green hue, and the form best adapted for its exhibition he found to be a decoction of a strength representing from ʒ j. to ʒ iij. of the powder.

The article was entirely harmless, was not an abortive, but acted as a sedative upon the uterine system, and proved its specific action by increasing the menstrual flow.

The experience of all the gentlemen, however, who had tested this agent was not uniform, nor as satisfactory as that of the reporter.

DR. CHAMBERLAIN gave the details of three cases—in one of which he had ineffectually exhibited ʒ iv. for five days—in the other two the results were negative.

DR. HUBBARD had hardly given this emmenagogue a fair trial; but in his solitary instance had employed ʒ iv. prepared after Mr. Dung's directions, and with no more success than the last speaker.

DR. PRINCE, in reply to a query by Dr. Bulkley, had found that the samples had varied in strength and excellence.

DR. HARRIS, in view of the fact as stated by Dr. Prince, that no chemical analysis had as yet been made, offered the following, which was unanimously adopted:

Resolved, that Dr. E. R. Squibb, of Brooklyn, be requested to examine this drug, and that he report to this Academy at his earliest convenience.

He thought that the alkaloid of Tsa-Tsin, if it had any, might possibly be discovered in this way, and with it the profession might experiment more satisfactorily.

After a recital by Dr. Harris of certain remarkable cases of anomalous fever which had occurred in the vicinity of this city, and which are now being investigated, the Academy adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

STATED MEETING, SEPT. 2, 1867.

DR. SAMUEL T. HUBBARD, PRESIDENT, in the Chair.

THE PUBLIC HEALTH.

DR. DUNSTER, as Secretary of the Committee on Diseases, read the report, which embraced a period of thirteen weeks, ending August 24th, ult. The average weekly mortality (519) during this time was less than the corresponding weeks of the previous year, and exhibited an actual decrease of sixty-four deaths. This was accounted for by the absence of any epidemic, and the favorable meteorological and sanitary condition of the city.

The zymotic diseases constituted in June twenty-nine per cent., in July forty-two per cent., and in August forty-seven per cent. of the entire mortality—in this class, diarrhœal diseases were the most destructive. During this period, however, cholera claimed only eighteen victims, against 834 of the previous year. Scarlatina and rubeola have been quite prevalent, the mortality from the latter disease averaging during the entire summer twenty per week.

The tubercular diseases show the unfavorable effect of extreme and prolonged heat—since in August the death-rate was equal to a figure attained during the inclement weather of February and March. On the other hand, the mortality ascribable to pneumonia and bronchitis had inversely declined.

During the thirteen weeks, 23·7 inches of rain fell, which, as it washed away vast amounts of filth, exerted a beneficial effect. This, however, would not have been the case if the city had an absorbing and retentive surface soil in lieu of an extended and perfect drainage.

PAPERS READ.

Dr. Noyes read a paper entitled "Recent Modifications of the Operation for Cataract, and their Results." This was statistical in character, and contrasted the different results as obtained by the ancient and by the modern methods. He clearly proved that the recent plans of treatment were much the more successful.

Dr. Thoms followed with a plan for the registration of atmospheric changes, adapted to the exhibition of their influence upon disease and mortality.

THE ANNUAL COLLATION.

The President announced that the next meeting of the Society would be its anniversary, on which occasion the annual election would be held. He also stated that the annual collation, which embraced within its plan a general reunion of the profession, would be had on or about that time, and appointed the following gentlemen a committee of arrangements to carry out the purposes of the Society: Drs. Wm. B. Bibbins, Ellsworth Eliot, James L. Brown, Jerome C. Smith, John Shrady, H. M. Brush, Wm. B. Lewis, and Wm. T. White.

The Society then adjourned.

EAST RIVER MEDICAL ASSOCIATION.

Stated Meeting, Sept. 3, 1867.

Dr. Verranus Morse, President, in the Chair.

THE DECEASE OF DR. JOHN HART.

Dr. T. Nichols reported resolutions of condolence upon the decease of Dr. John Hart, a former President of the Association, which were ordered to be published in the medical journals of this city.

Dr. Morse spoke in eulogistic terms of the deceased, and gave an account of his last illness, together with many incidents of his life.

UNAUTHORIZED REPETITION OF PHYSICIANS' PRESCRIPTIONS.

Dr. John Shrady presented the following, which was adopted:

Resolved, that in view of the meeting of the American Pharmaceutical Association on the 10th inst., it is eminently proper that the action of this Association regarding the unauthorized use of physicians' prescriptions by apothecaries be referred to the former body.

GRADUATES OF AMERICAN MEDICAL COLLEGES, AND THE GERMAN SOCIETY OF NEW YORK.

Dr. Brekes introduced the following, which were also adopted:

Whereas, it has been represented that the German Society of the City of New York have resolved that no graduate of an American Medical College shall be appointed to the position of District Physician, therefore be it

Resolved, that the Association, through their committee, ask for information on said subject, and respectfully request the reasons for said action. Committee, Drs. Brekes, Weisse, and Blume.

Dr. Weisse then read the report of the Surgical Section, in which he gave an interesting and condensed summary of the progress of that department of science for several months past.

DIFFICULTIES IN DIAGNOSIS OF ABDOMINAL TUMORS.

Dr. O'Sullivan read a paper with the above caption. He warned against a too great haste in diagnosis, especially with reference to tumors in suspicious localities, and recited an instance where a popliteal aneurism was laid open instead of an abcess. This necessitated immediate amputation, death ensuing in a few days.

In regard to the abdomen, notwithstanding the publication of many interesting cases implicating some particular organ of the cavity, he was somewhat astonished that the question in its general bearings had never been discussed. A notable exception, however, exists in the case of the *American Medical Association* (see Medical Record, vol. ii., p. 130), who have deputized a committee to investigate the subject. For the purpose of more fully illustrating his views, he related

A CASE OF CARCINOMA OF THE LIVER OF SIX MONTHS' STANDING.

Some years ago he was consulted by S. P., a native of Canton, China, who first came to America in 1816, in the capacity of ship's steward or cook. For the past sixteen years of his life, however, he kept a Chinese sailor boarding-house in Cherry street.

He was married twice; by his first wife he had no issue, by the second three children, all of whom are living. He enjoyed, for a considerable time previous to his last illness, excellent health. Some eighteen years since, whilst on a voyage from New Orleans to this port, he met with an accident which caused a severe contusion of the right side; owing to which, on his arrival here, he entered the hospital, where he remained several weeks.

According to the rather general custom of his countrymen, he was an inveterate opium smoker, but during his last illness he practised this rather moderately. In other respects, the history of the patient, owing to his imperfect knowledge of our language, is necessarily incomplete.

When he first consulted Dr. O'Sullivan, he referred his trouble mainly to the region of the stomach, where there was a very strong pulsation; he also complained of pain in the chest, being unable, however, to localize it. He also suffered from constipation, which had become habitual in its character. A careful examination of the lungs and heart revealed nothing abnormal. Still pursuing his investigations, he discovered a large tumor in the epigastric region, below the diaphragm, and in a line with the transverse colon.

It presented a nodulated appearance, and its extent, he fancied, could be quite readily traced. Auscultation elicited no thrill or other symptoms of aneurism. Percussion elicited dulness over the entire extent of the tumor. The usual symptoms of carcinoma were absent. It then occurred to him that it might be a fæcal accumulation; this seemed the most probable theory from the history of the case, the position of the tumor, and its painless character. This idea, also, after a fair trial, he was reluctantly obliged to reject.

On examination of the tumor, after an interval of several weeks, during which the patient had omitted to call at his office, he found that it had increased somewhat in size, also that it was a little tender on pressure; in other respects the symptoms had undergone no change. After a careful examination by a physician of eminence, whom he had called in consultation, the latter inclined to the belief that it was a fæcal tumor, but stated his opinion with some reservations, and advised saline cathartics, to be followed by injections, etc.

Free movements of the bowels, without any appreciable effect on the tumor, were the only result. As this plan of treatment only debilitated, it was, with the consent of the consulting physician, suspended. The patient was frequently seen during the month, during which time he complained of very little pain in the tumor, and scarcely any irritation of the stomach; he could retain his food very well, though his appetite was somewhat fickle; occasionally, too, the loss of sleep troubled him very much. To meet this indication, he prescribed a pill of camphor and hyoscyamus, which for a time seemed to relieve him; he was also taking at this time a bitter (fluid ext. quassiæ), and locally he had applied a belladonna plaster, etc. A messenger, who came with an urgent solicitation at 11 P.M. a month after, stated that the patient had been injured in a *mêlée* at their house a short time previously. On arrival, Dr. O'S. found him suffering much pain, kneeling in bed and resting on his face and hands, which position, with much difficulty, he succeeded in getting him to change. He then ascertained that his Chinese patient, whilst in the act of leaving his room, in a fit of anger was pulled back by an excited female relative, who seized him by the waist, and thus made direct pressure on the tumor. From thenceforward he continued to complain constantly of pain, his stomach, however, behaving as well as usual. About this time a surgeon of eminence, now deceased, saw him, and pronounced in favor of an aneurism, although he confessed that the symptoms were not as well defined as usual. He advised a continuance of the same line of treatment. The pain and uneasiness in the region of the tumor, however, seemed to have increased; and the patient, a little despondent, and naturally enough anxious for a change of remedies, desired further counsel. Accordingly, Dr. E. R. Peaslee was called; and, after a thorough examination of the case, very decidedly excluded aneurism. He thought it probable that the growth, whatever it was, was attached to the left lobe of the liver; as to its character, he could not determine. This opinion was also expressed by the late Dr. Sinclair, who saw the patient a few weeks before. The patient continued in this condition some days, feeling pretty comfortable, being able to walk about his room, and seemingly not suffering much from debility or loss of flesh, having even gone to Brooklyn on a visit to some friends for a couple of days. His daughter stated to me that he would have remained some time longer, but for the want of his opium pipe. He finally died in a semi-comatose state; and three and a half hours after death, Dr. O'Sullivan, assisted by the late Dr. D. S. Conant, made the autopsy.

After opening the abdomen, the peritoneum on the upper part of its cavity was found in a state of great congestion, and considerable ecchymosis existed in the epigastric region. The large tumor which had caused so much diversity of opinion previous to death, was found to be connected with the left lobe of the liver; turning just below the mass, the transverse colon crossed the abdomen, whilst, resting upon the lower projecting portion of the growth, the pylorus and duodenum crossed in the direction of the mass, which was readily dissected up from the aorta, and removed with a portion of the pancreas, which was adherent to its lower border, by making a section of the liver through the longitudinal fissure. The abdominal aorta was then dissected out from below the bifurcation to the middle of the thoracic aorta, and found to be almost perfectly healthy. The accompanying specimen he brought away, not without the consent of all concerned, but amid the howling of the excited Chinese. Specimens of the contents of the lower cystic and divided portions of the preparation, have been examined by Professor Flint, Jr., and found to be composed of cancer cells, free nuclei, fatty globules, and granular matter, as were shown in the accompanying diagram.

After some debate upon the paper, the Association adjourned.

Progress of Medical Science.

NEW METHOD OF PRESERVING FLESH.—Dr. Brunetti, of Padua, has discovered a new method for preserving flesh, for which he has been awarded a gold medal at the International Exhibition. The following description of the process is given by the Paris Correspondent of the *N. Y. Times*:—The process of Dr. Brunetti comprises several operations, viz.: 1, the washing of the piece to be preserved; 2, the *dégraissage*, or eating away of the fatty matter; 3, the tanning; and 4, the desiccation. 1. To wash the piece, M. Brunetti passes a current of pure water through the blood-vessels and the various excretory canals, and then he washes the water out by a current of alcohol. 2. For destroying the fat he follows the alcohol with ether, which he pushes, of course, through the same blood-vessels and excretory ducts; this part of the operation lasts some hours. The ether penetrates the interstices of the flesh, and dissolves all the fat. The piece, at this point of the process, may be preserved any length of time desired, plunged in ether, before proceeding to the final operations. 3. For the tanning process, M. Brunetti dissolves tannin in boiling distilled water, and then, after washing the ether out of the vessels with distilled water, he throws this solution in. 4. For the drying process, Dr. Brunetti places the pieces in a vase with a double bottom filled with boiling water, and he fills the places of the preceding liquids with warm, dry air. By the aid of a reservoir, in which air is compressed to about two atmospheres, and which communicates by a stop-cock and a system of tubes, first to a vase containing chloride of calcium, then with another heated, then with the vessels and excretory ducts of the anatomical piece in course of preparation, he establishes a gaseous current which expels in a very little time all the fluids. The operation is now finished. The piece remains supple, light, preserves its size, its normal relations, its solid histological elements, for there are no longer any fluids in it. It may be handled without fear, and will last indefinitely. The discovery is a magnificent one, and the sooner medical schools are provided with full cabinets of natural and pathological pieces the better.

TREATMENT OF SCROFULOSIS.—Dr. T. Balman (*Lancet*) proposes a treatment for scrofulous disease of the external lymphatic glands which consists in the local application of pledgets of lint soaked in *iodine*. If the disease be chronic, pencil with *argent. nitr.* every five or six days. When abscess forms, open at once, apply lint, and paint with iodine.

THE CAUSE OF RACHITIS.—Dr. Dick, in a communication to the Pathological Society, London, proves rachitis

to be a disease of mal-nutrition of bone. He experimented on puppies—taking certain ones of the litter from the mother's breast, and raising them by hand; in these he produced the disease artificially, while the nurslings were exempt.

A Question regarding Nutriment.—Dr. Thudichum asserts that Liebig's extract of meat lacks the essential properties of nutriment. It contains the elements required in very small proportion, and in an oxydized state, and is simply a stimulant, a strong beef-tea when prepared for swallowing. Of the twenty-five per cent. solid substance contained in meat, four-fifths are insoluble in water, or become so by boiling, allowing only one-fifth of the solid parts, or five per cent. of the whole, to be saved in the extract. He thinks that, after eggs, the nearest substitute for meat is Indian-corn and other kinds of seeds, beans, peas, etc., when grown in southern climates. Northern grown beans are not approved, and this kind of food always requires peculiarly careful preparation to be digestible. Vegetable food requires much digestion, and its use demands and creates an increase of the stomach, which is visible in well-fed vegetarians.

Fish Biscuit.—Professor Rosing, of Asa, France, has invented a process of making flour from a species of sea-fish, which he forms into biscuit, thereby providing a very nutritious and compact article of food. These biscuit are four times as rich in albuminoid substances as beef, four and a half times as fresh codfish, and sixteen times as fresh milk.

Weaning—A writer on this subject, in a communication to the Boston *Medical and Surgical Journal*, says: "The best average I can make, gives almost eleven months as the approved term for lactation. But eleven months is a longer period than I would have, as a rule, in the present state of society. Children weaned at nine months do as well as those weaned at eleven months, for aught I have discovered, and three months will, in many instances, be added to it from a variety of causes; and if a longer term than nine months is named, just as much will be added to that, and lactation will be prolonged to a very doubtful period.

"I suggest nine months—not as prefigured by gestation, or anything else, but simply as a reasonable term for nursing. In support of a shortened term of lactation, I have an impression, strong enough to influence me a good deal, that children nursed beyond a year—above all, for two years—are not likely to do as well as those weaned earlier; and that scrofulous or puny children are not benefited by an extended term of nursing, especially of their own mothers; and, on the other hand, that mothers are generally benefited by a brief term of lactation.

"The advancement of the teeth is generally made an item in deciding the question of weaning. The age for the development of the canine teeth—the most dreaded period of dentition—is about the eighteenth month; and to wait for the appearance of those teeth, would be to establish an unreasonable term of lactation.

"On this point of the importance of the development of the teeth, writers are very indefinite; and each writer who does specify what teeth he would have the child exhibit at the time of weaning, states that children usually show the specified teeth at about the age he has named as the fit time to stop lactation; so that in fact the cutting of the teeth comes to be a part of a cautious theory, but is in reality of very little consequence in deciding whether a child should be weaned or not."

On the question of the season of the year when a child should be weaned, the same writer says: "The suggestions of Dr. Dewees, which divide the year into a convenient, an inconvenient, and an improper season, were based on a large and careful observation, and are well worth remembering. If we look, however, for a formula on the season, we shall hardly find anything more concise than the words 'either after the warm season has passed, or before it has commenced. Of the two I prefer the former.' I will only add for myself, that (so strong is my conviction that much nursing is not welcome by the mothers of this day), I would not hesitate to wean in the spring. If a child is nine months old early in May, I would advise that it be weaned, unless its mother exhibit uncommon capacities as a nurse. But each case of weaning, like each case of sickness, is to be considered and managed by itself, and not to be disposed of in rigid accordance with any fixed rules or maxims."

Persistent Eclampsia; Forced Delivery Accomplished by Bilateral Incision of the Cervix Uteri.—Wm. P. Holt, M.D., in the *Southern Medical Journal* relates the history of a case to which he was called, where the patient was "a primipara aged 19, stout, robust, and very plethoric." She had had "grinding pains" for several hours. An examination revealed the os high up, *undilated* and rigid. Had had great fulness about the head for three weeks, and the limbs were œdematous. Four hours after the first examination, the os was found in the same position and condition. Convulsions came on soon after, which were modified, but not controlled, by chloroform. The convulsions still continuing, it was decided to take blood from the arm, which was done copiously; but the convulsions again recurring, it was decided to make a bilateral incision of the cervix uteri with the probe-pointed bistoury, forcibly dilating with the finger. A hook was then introduced, the fœtus caught in the groin (it being a breech presentation) and delivered. The after-birth soon came away entire, and the patient made a good recovery.

Treatment of Opium Poisoning by a New Method, by A. Le B. Munroe, M.D.—A lady had taken two ounces of laudanum, from the effects of which she was in a state of profound *coma*. Emetics were used, and afterward the stomach-pump was applied, and the stomach thoroughly worked out, which produced no amelioration of the symptoms.

The following treatment was then instituted: "The patient was placed upon her back on the floor, with her head elevated a little upon a folded sheet, the clothes slipped down below the waist, leaving the chest entirely bare. A pail and a pitcher of cold water were then brought in. The pitcher was then raised to the ceiling, eight or nine feet from the floor, and the water allowed to fall in a small stream upon the epigastrium. By the time the first pailful was exhausted, the breathing had become a little more frequent and equable, and the stertor less. The second pailful was brought in, and soon, to my great joy, I could see that the deathly pallor of the face was being lighted up by the flow of the vital current from the heart; a blush, barely perceptible at first, gradually and steadily spread over the before pale and expressionless features, until it warmed into the full glow of life and health. By degrees other manifestations of returning life appeared. She began to make efforts to move away from the pouring stream, weak at first, but increasing in strength, until she could turn partly over and interpose the hands to break the force of the stream. At length, after about three pailfuls of water had been used, her struggles to escape from what was now evidently torture, were quite severe;

and about this time, to our infinite satisfaction, she began to beg for quarter in long-drawn, drowsy syllables, increasing in energy and force, until they were uttered in a tone and manner which evinced a considerable degree of passion, and even anger, at the strange and even cruel treatment to which she was subjected. But even now she would fall asleep immediately if let alone. Having continued it as long as we thought necessary, we desisted, and rubbed her dry with warm cloths. We then raised her up and walked her about the room for an hour or more, resting at intervals. She recovered without any permanent ill effect.

"I believe this treatment will be more effective in the cure of extreme cases of opium poisoning than anything else. Doubtless it would be just as effective in poisoning by other narcotics, and possibly in some cases of suspended animation."—*Boston Medical and Surgical Journal.*

CROUP TREATED BY SULPHUR.—*The British Medical Journal*, quoting from the *Gazette Med. de Paris*, states that M. Lagonterie, from observing the effects of sulphur on the oidium on vines, has been led to administer it in several cases of croup. He mixes a teaspoonful in a glass of water, and gives the mixture in teaspoonful doses every hour. The effect he describes as wonderful. The disease, in effect, is cured in two days, the only symptom remaining being a cough, arising from the presence of loose particles of false membrane in the trachea. Mons. Lagonterie says he has followed this plan in seven cases, all being severe, especially the last, the patient being cyanotic, with protruding, rolling eyes, and noisy respiration.

HYDATIDS OF THE UTERUS.—Dr. W. H. Grimes, in the *Leavenworth Herald*, states that he attended a patient where there were expelled from the uterus fourteen pounds of hydatids. "The woman was a good deal exhausted by protracted suffering and subsequent hæmorrhage; this condition, however, was soon relieved by cold application, and repeated doses of tannic acid and morphine. She rapidly recovered, and has had no further trouble from the disease."

LEPROSY.—Surgeon C. Macnamara, of the Calcutta Hospital, draws the following conclusions in regard to this disease: 1st. Leprosy is very common among the natives, about one in ten being affected byit, and it is probably on the increase. 2d. It is much m ore common among the pure natives than among other tribes which have become degraded by intermarriage with them, and it is very rare among Europeans. 3d. It is hereditary and inoculable, but not propagated by simple contact, or through the air, or by sexual intercourse or other means. 4th. It has no connection with syphilis, and was prevalent in India centuries before that disease was known. 5th. It is probably curable in its premonitory stages, but in the anæsthetic or tubercular form it is without remedy. No provision having been made by the Indian government for the care of lepers, much remains to be learned regarding the treatment. 6th. A proper regard for cleanliness and other hygienic considerations seems amply sufficient to prevent the disease.—*Pacific Medical and Surgical Journal.*

GRINDELIA IN ASTHMA.—Since our former notice of this plant in asthma, we have testimony from various sources which settles the question of its value. It appears to have been uniformly palliative, if not preventive, of the paroxysms in the cases treated by it. Its action seems to be antispasmodic and expectorant. In the case before referred to, in which the relief was so well marked, it lost its effects measurably after use for six months, though the paroxysms have never been as violent since as before the use of grindelia. We may mention here, that the best treatment known to us for true spasmodic asthma is the hypodermic injection of morphia. The paroxysm is invariably relieved by the injection, and, in a large proportion of cases, does not return for weeks or months. One-fourth to one-half a grain is the proper quantity. With this remedy we approach an asthmatic patient in the hope of giving him prompt and efficient relief. We usually inject it in the arm.—*Pacific Medical and Surgical Journal.*

CANNABIS AS AN ANTIDOTE FOR STRYCHNIA.—The *Chicago Medical Examiner* reports the case of a man who swallowed five grains of strychnia, and was seen nearly four hours afterward, when he had frequent and severe spasms, with rigidity of muscles, and inability to move the limbs; pulse 130. A drachm of the tincture of cannabis was given, and another in five minutes; then two similar doses at intervals of ten minutes, and two doses at intervals of fifteen minutes, with rapid amelioration of the symptoms. The next drachm was given in an hour and a half, after which it was alternated with camphor, as the symptoms demanded. The patient recovered with uninterrupted convalescence, after forty-eight hours.

THE EXTRAORDINARY DELICACY OF THE SPECTRUM TEST in determining the presence of certain metals is well known to scientific men. Bunsen and Kirchhoff intimate that it is possible to recognize in this way the sixty-thousandth part of a grain of potassa or baryta, the one-millionth of a grain of lime or strontia, the sixty-millionth of a grain of lithia, and the one hundred and sixty-millionth of a grain of soda. Dr. Letheby, the distinguished London chemist, has detected by these means, the presence of blood in the stains on linen which had lain by for seventeen years.—*Pacific Medical and Surgical Journal.*

TANNIN AS A HÆMOSTATIC.—Dr. J. M. Linley, in the *Leavenworth Herald*, thus speaks of tannin: "A man, 54 years of age, was presented to me with gangrene of the foot. The line of demarcation was well formed, just above the ankle. I amputated the leg at the middle third. The arteries were easily secured, and no arterial blood was lost, but the venous hæmorrhage was considerable, and soon increased to frightful proportions, although several of the larger veins were secured. I sprinkled tannin over the surface of the wound, and the hæmorrhage was immediately and permanently arrested."

SEPARATION OF TIN AND ARSENIC.—Professor Wöhler's method is based on the solubility of sulphide of arsenic in bisulphate of potash, which does not dissolve the tin. The mass, after being oxidized by nitric acid, is allowed to digest with sulphur and caustic potash till the solution is complete. The liquid, after being treated by sulphurous acid in excess, is allowed to rest for some time, and is then evaporated until all the sulphurous acid is driven off. The sulphide of tin is then removed by filtration, and washed with a strong solution of common salt, which may be removed from the precipitate by an acid solution of acetate of ammonia. The sulphide of tin is converted into the oxide of tin by roasting in contact with air. Arsenic may be precipitated from the arsenious acid contained in the liquid by a current of sulphuretted hydrogen.

TREATMENT OF BURNS.—The treatment for this class of affections in St. Thomas' Hospital, London, is to whitewash the parts with a paste of whiting and vinegar. The crust is left on until it falls off, when a renewal of the application, if necessary, is made.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

GEORGE F. SHRADY, M.D., EDITOR.

New York, October 15, 1867.

THE LATE INTERNATIONAL MEDICAL CONGRESS.

IT seems that the grand international medical reunion at Paris failed to respond by substantial results to the zealous anticipations of many of its warmest friends. Such might have been presaged from a knowledge of the traditional routinism of certain leading spirits of the French school, and from the intellectual vassalage which restricted the free interchange of ideas, and community of thought within such limits as traced by the organizers of this universal medical convention. The conception of assembling the medical celebrities of all parts of the world—each to contribute his share of knowledge and experience, and offer it as a voluntary homage of his nation, and as an individual expression of charitable feeling and disinterested philanthropy—was the prompting of generous and noble impulses, and elicited the commendations and hearty support of the medical profession generally. The medical representatives of the different nationalities met in the enlivening capital of France, regaled by the brilliancy and magnificence of the gay city, favorably impressed and most indulgently disposed to justify to a moderate degree the gratification of a certain vanity so characteristic of Frenchmen, which at times is not displeasing, because attended with so much good feeling. But lo! Bouillaud, the President of the Congress, at its inauguration informs the assembly that "France is Paris, and that Paris is the World," and thus unmistakably exhibits the true motives which actuated the organization of the grand Congress. The President utters an expression of conceit which shows that none are welcome who are not convinced of the insufficiency of their own offerings, and humble enthusiastic admirers of certain French declaimers, who, having selected their own programme, chosen their own subjects for discussion, may very naturally be expected to eclipse the foreigners, most of whom probably are but imperfectly acquainted with the French language.

Our Paris correspondent has faithfully exposed the proceedings of the Congress, which will be read with interest. Impartiality requires that we should adjudge a just meed of praise for the benefits resulting from the discussion of those subjects which occupied the attention of the Congress, although regretting as we do that the organization was so imperfect, disappointing the hopes of many of its well-wishers, both among Frenchmen and foreigners.

One of the questions which appears to have received most attention was, the several complications occurring after surgical operations, and which so frequently cause death. The subjects of tuberculosis, of syphilis, and of syphilization, called forth animated discussions. Menstruation and the preservation of anatomical specimens, although important subjects, engaged the attention of the convention, to the exclusion of other and more weighty matters. At the first meeting, Dr. Van Lohe, of Holland, expressed, in energetic and sensible terms, his disapprobation of transforming the International Medical Congress into a school of medicine, where were pronounced learned dissertations, affording no instruction to any one, but serving merely to display the mutual admiration of certain members. President Bouillaud, in calling the refractory member to order, discovered the sentiments of a large portion of the assembly, and which were manifested by its hearty approval of the intrepidity of the honest Dutchman. It was fortunate that there were some who, if they did not fully represent the medical celebrities of their respective countries, might at least enter a protest against the proceedings of the assembly. No idea can be formed, from a review of the deliberations of this learned body, either of the importance of our own country, or of its claims to a proper and merited distinction. The same, with rare exceptions, may be said of other countries. These remarks are not prompted by a spirit of detraction; on the contrary, the recollection of the great and valuable advances in medical science made in France will cause us always justly to esteem the names of those great men like Bichat, whose giant intellect in a few years regenerated the medical science; Laennec, who discovered and developed auscultation; or who, like Dupuytren, gave a practical value and brilliancy to surgery, and which reflected the highest honor on the profession.

These, and a host of other great men who have added lustre to the French school, have passed from the stage of life; and some have but quite recently, like the last falling leaves of autumn, seemed to drop all at once: Malgaigne, Trousseau, Civiale, Velpeau, Rostan, Rayer, have gone to their last homes, and left but the relic of the past, the President of the International Medical Congress, M. Bouillaud.

The excellence to which the French have attained in their physiological, pathological, and chemical researches, have rendered them eminently distinguished, and caused them to be accepted as the leaders in medical science. Frenchmen have been for a long time, to a very considerable extent, the elaborators of the important

problems which have engaged the minds of medical men; they have been large contributors to our science; but not the only ones. With the march of intellect and the extension of civilization; with the astonishing enterprise displayed in all the departments of industry throughout the world, and especially on this Western Continent, an influence has been exercised upon the progress of medicine commensurate with the general development of intelligence, and the multiplied comforts and conveniences of life. The medical profession of this country is in a position to be a large contributor of valuable knowledge to any international medical congress; and if the organizers of the Paris Congress failed to recognize this fact, others have not. French surgeons now adopt our American operation for ovariotomy, and Frenchmen pay a tribute of respect in many ways to our countrymen. Our ambulances are esteemed the best at the Paris Exhibition; our sewing and reaping machines, with other appliances of industry, which are the real exponents of a true civilization, have been adopted by the French, and the Imperial Government supplies its navies from our iron-clads. Well might the International Medical Congress have anticipated important advantages from a better acquaintance with the progress of medical science in this country, suggestive, at least, if not fruitful in brilliant scientific results.

During the threatened cholera epidemic, we heard much through the secular, as well as the medical press, of the praiseworthy sanitary labors of our Board of Health. Disinfection and purification, zymotic diseases, contagion through the moisture of the earth, were terms well set forth in exhaustive reports, famed for verbosity as well as for zeal in the sanitary reform of our metropolis.

But if all the rumors which reach us have a tithe of truth in them, some of our health authorities are resting with their laurels won, while nuisances in the way of filthy gutters, excrements thrown into the public streets, are left to breed fever and death, with no sanitary inspector "to molest or make afraid." Policemen say that remonstrances are made in vain, and citizens inform us that in individual instances respectful complaints have not even been noticed.

Seriously, gentlemen of the Board of Health, every complaint of a respectable citizen deserves a careful investigation, and, if possible, the nuisance should be promptly abated. Inspectors have other duties than to draw their pay and wear their badges. The city of New York deserves a little more sanitary inspection than that involved in carefully prepared reports and statistical tables. There are crying evils in the city, which the capable medical men engaged as inspectors should daily report until they are abated. After a great struggle, some of our first medical men have been placed on a Board of Health, a band of well-educated inspectors selected, but, in some instances, they pay no more attention to honest complaints, they see no more nuisances in their sessions and rounds, than did the former company of liquor dealers who did our sanitary inspection.

The intentions of the Board are doubtless good enough, but it strikes us that its heretofore fair record is liable to be seriously damaged in the eyes of its firmest upholders by the apathy into which it has seemingly so lately fallen. Eternal vigilance is no less the price of liberty than of health, and we fear that our Health Board needs the monition.

We regret being compelled to notice a severe attack of publicity which one of the professors in a medical college of this city has recently been subjected to, in the columns of the *Evening Mail* of October 7. We are willing, for the sake of the dignity of the profession which he represents, and for the respectability of the number of institutions with which he is connected, to strain our charity, by presuming that he is entirely innocent of any complicity with such a flagrant breach of good taste and medical etiquette. If our presumptions are well founded, and we sincerely hope they are, who among the profession can be considered safe from penny-a-liners in search of items; who can rest assured that, at some future date, the number of his surgical operations may not only be peddled to the community, but that the very privacy of his home be invaded, letting alone the recital of many other details, the bare perusal of which in print would be calculated to bring the blush to his cheek? But if there is no escape, let us prepare ourselves for the worst.

The yellow fever at the South still prevails to an alarming extent, especially in New Orleans and in the interior towns of Texas. In the former place the mortality has been terrible, the number of vicitims to the disease, up to the first of October, being estimated at the enormous number of seventeen hundred and seventy-six. At Galveston and Corpus Christi, the fever, by all accounts, has spent itself, there remaining only a few scattered cases; but in the towns of Lagrange, Huntsville, Hempstead, Mellican, Alleyton, and Navasola, in Texas, it is still at its height. At Hempstead and Alleyton all the physicians are dead, and at Mellican during the past month the mortality has been fully seventy per cent. The different Howard associations are doing their work in a manner that reflects credit upon their name, and the physicians are nobly striving with all their energies and skill to stay the progress of the dreadful enemy. The associations referred to hold regular daily sessions, and the amount of labor that they perform may be in a manner apppreciated when, on the authority of the *N. O. Times* of the 26th inst., we state that twenty-five hundred cases have been on the relief books at one time, and that, on an average, over seventy cases have been reported during each day.

It is estimated that the "Howards" of New Orleans alone will have to spend seventy-five thousand dollars

before the season is over. In view of this fact the amount of pecuniary aid that is needed will be apparent to all. We are, however, pleased to hear that money is being subscribed with a liberal hand for those localities where it is so much needed, and given in the hands of those who use it so wisely. In this connection we may mention particularly that the N. Y. Academy of Medicine recently forwarded the sum of thirteen hundred dollars to the Crescent City, and that the Medical Society of Richmond Co., N. Y., has arranged to send out two of their number to aid their worn-out brethren. It is hoped that the coming frost may soon put an end to the scourge, and that the stricken localities may speedily be released from that appalling gloom which has hung over them for such an unusually long period.

In view of the painful interest now taken in the origin and spread of the epidemic, we have thought it advisable to publish in the present issue a verbatim report of the very interesting lecture on yellow fever recently delivered in this city by Prof. Stone of New Orleans.

Reviews.

A Treatise on Human Physiology, designed for the Use of Students and Practitioners of Medicine. By John C. Dalton, M.D., Professor of Physiology and Microscopic Anatomy in the College of Physicians and Surgeons, etc., etc. Fourth Edition, Revised and Enlarged, with 274 Illustrations. Philadelphia: Henry C. Lea. 1867. 8vo, pp. 678.

Prof. Dalton's work has such a well-established reputation that it does not stand in need of any recommendation. Ever since its first appearance, it has become the highest authority in the English language; and that it is able to maintain the enviable position which it has taken, the rapid exhaustion of the different successive editions is sufficient evidence.

The present edition, which is the fourth, has been thoroughly revised and enlarged by the incorporation of all the many important advances which have lately been made in this rapidly-progressing science.

Injuries of the Eye, Orbit, and Eyelids, their Treatment and Remote Effects. By Geo. Lawson, F.R.C.S., Eng. Assist. Surgeon to the Royal London Ophthalmic Hospital, Moorfields, and to the Middlesex Hospital; Late Assist. Surgeon, Rifle Brigade. With numerous illustrations. Phila.: H. C. Lea. 1867. 12mo, pp. 408.

The welcome which this book has received across the Atlantic, has induced its republication in this country, and that it will be equally well received by us, there can hardly be a doubt. The work comprises a collection of all the more important and frequent injuries of the eye, selected evidently with great care, most of them being typical in character. All the different important operations for the removal of deformities and the like, occasioned by injuries, are succinctly described, and most of them elaborately illustrated. Although evidently intended for the specialist, the work will be found of special value to the practical surgeon, to whom ample directions are given for the performance of most, if not all, the necessary operations. Very many of the cases are unique in character, and all are interesting, and as a majority of them make their first appearance in print, a special practical value is thereby given to the work. Every one who consults this *brochure* will arrive at the conclusion that the author has performed a very useful task excellently well, and has spared no pains to dish up for his readers a pleasing variety of cases, each of which has its own practical value. The numerous well-executed illustrations serve to add to the interest of the work, as well as the addition in the latter part of the volume of the test types of Jaeger, of Berlin

Diagram Showing the Effects of the Meteorological Influences on Mortality in the City of New York, 1866. Arranged by Wm. Faulds Thoms, M.D., Physician to the N. Y. Dispensary, Surgeon to the Eastern Dispensary, etc. Wm. Wood & Co. 1867.

This chart, with a surface of only one and a half square feet, represents a deal of careful compilation, and addressed as it is to the eye, conveys to the mind at a glance the various relations to each other of rates of mortality and temperature as influenced by barometrical bearings and points of humidity. The perpendicular lines divide the diagram into months and weeks, while the horizontal are used as a scale for mortality, temperature, etc. The waved lines, stars, and figures, indicate the variations in the meteorological influences and their effects on the mortality. For example, the record for the week ending July 31st (29th week), shows the interesting fact that the mortality rate is greatly increased when high temperature is combined with low mean humidity. We find, too, that during the cholera epidemic the barometer was relatively lower than usual; that westerly winds, and vernal rains, barring perhaps the element of coincidence, slightly increased the death returns. During autumn, however, falls of rain appear to exert quite a contrary effect. Deaths, too, are less frequent when the thermometer ranges between 60° and 70° Fahrenheit, the barometer being at 30.00 inches, and the mean humidity between 60° and 70° (taking the point of saturation at 100).

A noticeable feature about the plan of arrangement is the facility of comparison between any given year, month, or week, thus making the science of meteorology thoroughly practical.

The Medical Use of Electricity, with special reference to General Electrization, as a Tonic in Neuralgia, Rheumatism, Dyspepsia, Chorea, Paralysis, and other affections associated with Debility. By Geo. M. Beard, M D., and A. D. Rockwell, M.D. New York: Wm. Wood & Co. 12mo, pp. 65.

This book has appeared in substance in our columns during the past few months. We assume, however, that this constitutes no valid objection to our notice of it, as independent reviewers. The subject is an interesting one, not only as regards the agent employed, but as to the diseases treated. Looking back at the long but not glorious career which "electricity in the cure of disease" has seen, we are not inclined to envy our authors, in their attempts to rescue it from the ways of quackery, into which it seemed to have almost hopelessly fallen. Yet Doctors Beard and Rockwell seem to appreciate their position as pioneers, as an extract from page 12 will show: "It is the duty, and should be the delight, of scientific men, to wrest the medical employment of electricity from the hands of these selfish harpies, and accord to it that honor to which its merits justly entitle it." This misuse of valuable assistances in diagnosis and cure, is a common thing with us, where medical men may be easily superficially educated, and where they are very often ready to throw distrust and reproach upon a subject which they do not understand. The only way to drive out quacks is to educate the profession on every point, up to the possible results from any agent in cure, minute investigation, or aid in diagnosis.

If this little book opens the eyes of the profession to what electricity is, the peripatetic and self-constituted professors of magnetism will soon find their occupation gone.

There is an "explanation of terms" in the beginning, which clears away some of the fogginess about the subject of "galvanic battery, the quantity, intension, or tension of electricity, galvanization, faradaization, the ascending and descending current," etc. We think, however, that our authors would have done better had they left faradization as Duchenne gave it to us; simply because, whether properly used or not, it has been generally employed, and medical men do well, as a rule, to leave etymology alone; but this is a small matter.

The causes of the ill success of physicians in using electricity are very graphically given. The gist of it is, that physicians, often like the laity, expect means of cure to act in a miraculous sort of a way, and not as the result of their careful and conscientious use, in the hands or under the immediate observation of the medical attendant. We have had so much experience in combating this kind of an unexpressed but entertained opinion, among our medical brethren, in another field, that it is with warm feelings we see the principle that it is not the means used, but the way of using them, which does the good, so clearly stated as in this *brochure*.

The hand is preferred as an electrode. "No instrument that human skill shall devise can ever equal the hand in flexibility and power of adaptation."

Although the cases related take up quite a large portion of the book, we are by no means inclined to regard them as the most valuable part of it; but so far as they go, they seem to show that whatever general electrization may do, it avails much as a *tonic*. Carefully and thoroughly employed, it will undoubtedly save much drugging, and relieve cases which must else go unbenefited.

In the rapid sketch of the book which the state of our columns makes necessary, we can say no more than that it seems to be the entering wedge toward the more thorough laying open of the important subject of which it treats. We trust that before many years, the authors will give the profession the further benefit of their studies and practice. We are fully aware of the valuable contributions of Professor Wm. A. Hammond to our therapeutical knowledge of electricity; but the book of which we have been speaking is so obviously different in its scope from their record of investigations, that we attempt no comparison.

The authors are among the first, if not the very first, to call attention to the tonic properties of general electrization. If they never do anything more, they have done a great work, opened a large field which is yet to be carefully cultivated.

THE CRIME OF INFANTICIDE is increasing in France; and on this account the juries who are called upon to deal with these offences have recently found their verdicts unaccompanied with any allusion to mitigating circumstances. Thus at the assizes of the Gironde a young woman of 25 has been condemned to five years' imprisonment, with hard labor, for throwing her new-born infant into the river; and another woman has been sentenced to eight years' penal servitude at Strasburg for disposing of her child down a water-closet. At the assizes of Saône-et-Loire a girl of 18 was committed to prison, with hard labor for seven years, for burying her child alive.

Correspondence.

THE INTERNATIONAL MEDICAL CONGRESS.

TO THE EDITOR OF THE MEDICAL RECORD.

PARIS, Sept. 9.

SIR—Now that the International Medical Congress has come to an end, it may not be inappropriate to review its proceedings, and endeavor to form an estimate of its results.

This task cannot fail to disappoint. It is acknowledged on all hands that the Congress was ill-organized, the programme arranged without sufficient tact, and the legitimate aims of the discussions almost entirely lost sight of. Evidently the great advantage to be gained by the discussions of an assembly of physicians from all parts of the world would be, that the contingent of information furnished by each should represent something peculiar to his country or school. Data, often painfully gleaned from the records of travellers, would be collected in abundance by medical observers resident on the spot, and offered to enrich the common treasure. Moreover, celebrated men, who had hitherto talked to each other across seas, and through the medium of books, would meet face to face, would familiarly converse with each other on the mighty labors by which their names, their fatherland, had been rendered illustrious, and derive mutual refreshment from the rare intercourse.

All this I say might have been expected. But the expectation has been very imperfectly fulfilled. In the first place only inadequate provision was made in different countries to send such men as should most justly represent the actual condition of national science. There should have been official delegates from the principal universities, who should have been distinguished from the crowd of mediocrities who might choose to attend, but who should not be mistaken for such representatives. From lack of such precaution, a multitude of opinions were advanced which were entirely undeserving the sanction of so solemn an occasion as this professed to be. Any one could speak, and any one did speak; and, as a rule, the more distinguished visitors held their tongues.

Not a word from Virchow or Graefe, who were both present; not a word from Bennett or Simpson. Indeed only two Englishmen are on record as having spoken, and not a single American. The debates were chiefly maintained by the French and Italians. This was probably in part owing to the very imperfect knowledge of French that prevails among us Anglo-Saxons, especially the Americans, and which, as I have had quite frequent occasion to observe, seriously interferes with the benefit they are able to derive from a few months' visit to Paris. But the silence also resulted, in all probability, from the fact that few had prepared themselves for a sufficiently long time in advance; as a consequence, the topics for discussion were developed in the most unequal and irregular manner. The minute anatomy of tuberculosis occupied two or three sessions, in which nearly all the speakers were French, who revived old disputes without reporting any researches made especially for the Congress. On the other hand, the three questions that seemed most peculiarly adapted for international discussion—the influence of various climates upon menstruation; the problem of acclimation; and the influence of alimentation—were only touched upon in the most cursory manner. As a whole, therefore, the Congress cannot

be said to have arrived at any valuable result. Nevertheless, two of the discussions—on the treatment necessary to prevent purulent infection after surgical operations, and on measures to be recommended to the governments of various countries to arrest the spread of syphilitic diseases—were exceedingly interesting; and in all the *séances*, various topics were incidentally developed that are quite worth recording. I shall endeavor to mention some of the principal, beginning with those which occupied the least time and attention.

The communications made on the subject of alimentation were, in accordance with the programme, all written in reference to pellagra. M. Bouchut has found on grains of wheat spoiled by the damp, a fungus very similar to that found in the same circumstances on the maize, to the consumption of which pellagra is generally attributed. He proposes to name this fungus *sporisorium tritici*. To obtain it, it is only necessary to place some wheat in a jar, and keep it damp.

M. Demaria believes that pellagra is not dependent on an accidental poisoning, but is a constitutional neurosis, dependent on hereditary influences and poor food.

The communications of M. Dropsy, of Cracovia, concerning the Polish Jews, and Mr. Kingston on the Anglo-Canadians, presented in the course of the discussion on tuberculosis, touch on a subject of more widely spread interest than the poison of the maize. Each tends to prove the enormous influence of animal food upon the preservation of health, especially from the ravages of phthisis. At Cracovia, the peasants are all healthy and robust, living much upon animal food. The Jews scarcely spend more than two sous a day for their nourishment, and never eat meat. Consumption makes such ravages among them that the race threatens to die out. In the same way in Canada, the French Canadians, who eat meat in excess, often three or four times a day, are declared by Mr. Kingston (an Englishman) to be a superb race of people; while their English neighbors, who live much more soberly, are infinitely more subject to tuberculous disease.

The question of acclimation was as much restricted as that of the influence of food, being limited to the investigation of the conditions necessary for acclimating Europeans in warm countries. M. Simonot read an interesting memoir on the subject. For him the difficulty did not arise from the heat of the climate, but the poisonous influence of miasm. Wherever that could not be destroyed, it was useless to expect to make permanent homes for white families.

M. Lombard, not adhering strictly to the question, communicated the result of researches on the laws of mortality in Europe, according to atmospheric influences. According to these, winter and spring is the most sickly season for all the north and centre of Europe, while the southern countries enjoy their excess of mortality in summer and autumn. In Europe, miasm still continues to be one of the most powerful agents influencing mortality, and it is an agent which in this country it is in the power of man to remove.

A number of carefully prepared memoirs on the question of menstruation were communicated; but, as most of them consisted mainly of statistical tables, they could not be read. The statistics that *were* read, by M. Lagneau and M. Joulin, accord very well with the established law, in virtue of which menstruation is known to be precocious in warm climates, and retarded in cold. In English India, the average age for the establishment of puberty is twelve years and six months. In Norway, sixteen years and four months. The supposed differences between different cities of France is shown to be trifling, Marseilles being only six months earlier than Paris.

Mr. Robert Cowie has made some curious researches upon menstruation in the Shetland Islands, and its connection with longevity. In this locality the menses are established at the same age as in Great Britain, while the *ménopause*, instead of occurring at forty-five or forty-six years, is deferred to a period varying from forty-eight to fifty-four years, fifty-one being the average. In connection with this, Mr. Cowie notices a considerable difference in the rate of mortality, as shown by the following table:

	Shetland Islands.	*Scotland.*
Above 70 years	= 33.55 per 100.	18.25 per 100.
" 80 "	= 20.00 "	7.05 "
" 90 "	= 5.03 "	1.00 "
From 95 to 105 years	= 2.68 per 100.	0.29 "

The discussion on tuberculosis was divided into three parts, severally referring to its pathological anatomy, its prevalence in different climates, and its treatment. Of these, the first received much the most attention, not because of its superior importance, but because it happens to be extremely *à la mode* at the moment, and more speakers had something to say on it. The debates touched on the following questions: First, the specificity of the tubercle; second, its identity with the products of inflammation; third, the precise seat of the granular deposit; fourth, the relation of the yellow degeneration to the gray or crude tubercle; fifth, and finally, two or three peculiar and rather bizarre opinions were advanced which had no relation with any of these points.

The question of the specificity of the tubercular deposit may be variously regarded. A special anatomical element may be sought, as characteristic of tubercle, but such an attempt was universally pronounced to be chimerical. On the specific character of the tuberculous product, either the gray or the cheesy may be attacked or defended, together or separately. Such a combat occurred, and was marked by a diversity of arguments, in support of a diversity of theories. Professor Crocq of Brussels, and M. Lebert, assimilate completely the tuberculous process to the inflammatory. M. Crocq began by declaring that the cellules of the gray granulation could be compared to nothing but the cellules of the lymph and lymphatic glands, the white globules of the blood, of mucus, and of pus; in other words, leucocytes, among which he did not hesitate to class them. In the granulations, these leucocytes are distinguished from pus, chiefly by the absence of intercellular substance; are small, because bathed by no liquid, and have only a single nucleus, on account of their low vitality. These leucocytes arise from the epithelial cells, or those of the connective tissue, and submit ultimately to fatty degeneration, etc.

The phenomena successively exhibited in the formation of these leucocytes, are identical with those of the cellular elements of inflamed tissues. When an organ is examined in which tubercles are developing, it is found strewn with vascular patches. Sometimes the centre is already consistent and elastic, and at this centre the tubercle is gradually formed by exudation, since vascularization and repletion of the tissues by matters destined to be exuded, is common to inflammation and tubercular formation. Moreover, in inflammation the cellular elements absorb new material, swell, become opaque, and finally give birth to new generations of cells similar to the leucocytes. These, either in the tubercle or inflammation, have four destinations. First, they are destroyed, and their materials reabsorbed; second, they are transformed into new connective cells; third, they swim in an intercellular liquid, and constitute pus; fourth, they undergo the fatty degeneration.

It results from these considerations (concludes M. Crocq), that tuberculization is by no means a specific disease, recognizing a vice of the blood for cause, but an affection of the same order as inflammations, and should be combated, like other phlegmasias, by antiphlogistics and revulsives.

Lebert's views are substantially the same, but are based on inferences derived from certain experiments made upon animals by injections of various substances under the skin. In eleven instances were used the products of chronic pneumonia, chronic adenitis apparently tuberculous, and tuberculous granulations of the lungs; two experiments with injections of pus; nine, the products of expectoration and of pulmonary caverns; ten injections of charcoal or mercury were made into the jugular vein.

The charcoal produced little *emboli*, followed by cellular hyperplasma, little granulations, and even multiplication of the epithelial cells and those of the connective tissue. The mercury provoked, besides, an inflammation of the vessels; here also, however, cellular hyperplasma, in the form of little granulations, and, when the irritation had reached a high degree, formation of solid inflammatory foci which ultimately suppurated and produced caverns.

The inoculation of morbid products excited a more severe local irritation, and also numerous granulations in different organs.

Hence, for Lebert, the tubercle strictly resembling the granulation thus artificially created, is a product eminently hyperplastic, and cannot be classed with accidental products properly so called.

After this exposition of the pure inflammatory doctrine of tuberculization, Hérard and Cornil rushed to the defence of their theory, which may be called modified inflammatory. For them, the gray granulation is the only characteristic lesion of tuberculosis which excites an inflammation, whose degeneration constitutes the so-called cheesy tubercle. Neither of these champions undertook the task of rebutting the views of Crocq or Lebert, but each addressed himself to that side of the doctrine which touched upon, and was contradicted by, that of M. Villemain. This physican has recently made some remarkable experiments on the inoculation of tubercle, and has succeeded in thus conveying the disease to rabbits. So far, his experiments tended to confirm (at least without the criticism afforded by those of Lebert) the doctrine of the specificity of the tubercular deposit. But, proceeding further, he professes to have obtained gray granulations, after inoculation with the yellow cheesy matter. In consequence of this, he renounced the views he had previously held in regard to that substance, and, no longer believing it to be a secondary inflammation, he concluded it to be a more advanced stage of the crude tubercle, thus returning frankly to the ideas of Laennec. Hérard replied that this cheesy pneumonia (*pneumonie caséeuse*) might be sufficiently stamped with the character of the granulation by which it was caused, to serve as material for infection; but such did not prove that it was identical with the granulation which could often be found in its midst, little changed.

M. Cornil attacked Villemain on another point, namely, in regard to the *seat* of the granulation. Villemain, in a memoir of some length, read at the first session of the Congress, declared that the greater number of granulations occupy the air-vesicles, herein again coinciding with Laennec. At the beginning of his researches, he had considered the contents of the alveoli as a product belonging to the pulmonary epithelium, and distinct from the granulation, which is the view actually held by Hérard and Cornil. But subsequently, M. Villemain became convinced that the membrane of separation between the alveoli was not homogeneous, but contained a special element identical in structure with the connective tissue. In this tissue were deposited the greater number of the granulations. He considers the existence of an epithelial layer at the internal surface of the alveoli to be extremely problematical.

Hence, he does not believe that the elements constituting the catarrhal or cheesy pneumonia are derived from epithelial cells, but from the nucleated cells of the membrane separating the alveoli. Being much crowded, these cells sometimes assume plane surfaces from pressure, so as to resemble epithelium; but they are never soldered together.

M. Villemain admits that the initial stages of tubercle resemble those of inflammation, inasmuch as the two external zones of the three that constitute a tuberculous nodosity, represent cells in different stages of development; but the two processes are to be distinguished by the terminations, which for inflammation is pus, for tubercle fatty degeneration. The similarity between the anatomical elements of these two states is, as M. Villemain justly thinks, no reason for identifying them.

M. Cornil denied point-blank that the tubercle was developed anywhere but in the lymphatic or adventitious tunic of the blood-vessels, especially at their bifurcation. This phenomenon (in tuberculization of the pia mater) is accompanied by two others: 1st. The multiplication of similar elements in the connective tissue of the pia mater which surrounds the diseased vessel; 2d. The coagulation of the blood, and the retrograde metamorphosis of the fibrine and blood-globules.

Cornil admits that in the lungs there is a development of elements in the interalveolar membrane. But, besides, he insists that the large pavement cells, perfectly free, measuring 0.015, are really epithelial, and cannot be confounded with the elements of the connective tissue, which are small, 0.004, agglutinated, intimately united by a homogeneous and granular substance. The first constitute the tuberculous pneumonia; the second the granulation.

A Hungarian physician, Dr. Bakody, warmly supported the views of Cornil. He moreover suggested that the tubercle developed especially in the summit of the lungs, because there the respiratory movements are less extensive, and the lungs cannot readily reject the mass of cells which form in the alveoli in consequence of inflammatory irritation.

The question concerning tuberculization in different countries and circumstances was then taken up. M. Marmisse read a memoir upon the influence of this disease on the mortality at Bordeaux. The influence of hygienic conditions is indicated by terribly eloquent figures Among 1,000 poor people registered at the *Bureau de Bienfaisance*, 625 die of phthisis, while the rich classes only yielded a tribute of 87 on 1,000 to this formidable disease.

I have already quoted M. Dropsy's remarks on the Jews in Poland, and Mr. Kingston's on the English in Canada. Dr. Homan, of Christiania, read a memoir on the disease in Norway, and its distribution in different sections of the country. The proportion of deaths from tuberculous diseases in Norway is about 162 in 1,000. The variations in different districts are from 79 to 226 per 1,000. Sometimes a great difference is observed between two neighboring districts, which cannot, then, be referred to difference of climate. Dr. Homan invokes syphilis as a powerful agent to explain this difference. The capital question of the treatment of phthisis received no new light.

I must not forget to mention, among the opinions independently broached, that of M. Empis, who invents a new disease called *granulic*, distinct from tuberculosis; and of a physician whose name escapes me, who declares the cause of tubercle to be excessive pressure in the blood-vessels, whereby the colloid matters in the blood are exuded in the form of granulations.

The second great question, on the prevention of accidents after surgical operations, was developed with much animation. Two principal opinions obtained: one the perfect efficacy of local treatment, the other the importance of minute constitutional care.

One of the most interesting memoirs read in support of the first theory was that of Professor Bourgade, of Clermont-Ferrand, on the employment of perchloride of iron. The capital fact from which the Professor reasons is the different effect produced by wounds made with a bistoury or with caustic. The latter are habitually innocuous; the former often followed by serious accidents of infection. Some surgeons have sought on this account to substitute the caustic for the bistoury; but that is impossible in a large number of cases, and the bistoury will always remain the surgical instrument *par excellence*. The problem is, therefore, to reduce the wound made by it to the same conditions as that produced by the caustic. This, according to M. Bourgade, is accomplished by means of the perchloride of iron, which combines intimately with the tissues, and forms over the wound a kind of magma solid and adherent, a species of plastic cuirass, which resembles both a coagulum and an eschar, which becomes hard and resistant, and only begins to separate by suppuration, the sixth, eighth, or tenth day after the operation. The following is the method for its application: When the operation is finished, and the arteries suitably tied, the wound should be washed and dried with the greatest care; and when the flow of blood is well arrested, the whole surface is covered with lint saturated in a solution of perchloride of iron at thirty degrees. It is essential that all parts of the wound, bones, muscles, cellular tissue, etc., receive the direct action of the liquid. The whole is covered with moistened lint.

When the tampons of lint fall, they show a blackish surface, covered with a thin eschar, which gradually detaches itself, revealing a pink wound in very good condition, already covered with fleshy granulations.

This method, of course, is only adapted to wounds uniting by second intention; but, in M. Bourgade's opinion, that is the only union possible in hospitals. Several surgeons expressed the opinion that the attempt to obtain union by first intention was rapidly being abandoned. The perchloride has been applied in 95 operations, all followed with success.

The accidents that are guarded against by the perchloride are more especially purulent and putrid infection, phlebitis, angeioleucitis, osteomyelitis, and consecutive hæmorrhages.

The perchloride is supposed to act by a light cauterization of the bleeding surfaces, and by effecting a solid coagulation even in the interior of the veins. There results an adhesive and obliterating phlebitis, which prevents the suppurative phlebitis, and opposes the absorption of morbid elements.

M. Barbosa, delegate from the Portugal government, read some extracts from an important statistical memoir on the operations practised for the last twelve years in the hospital St. Joseph, at Lisbon. They were quite favorable—only 59 deaths among 243 amputations of limbs; among these, 62 amputations of the thigh, which gave 29 deaths.

M. Barbosa lays great stress upon the good hygienic conditions of the wards, ventilation, and cleanliness. He adopts the circular method for amputation, and always dresses the wound with lint dipped in alcohol saturated with camphor, an ancient custom in Portugal.

Professor Gosselin followed Barbosa in attaching much more importance to these circumstances of hygiene than to the local dressing. He takes especial pains with the *morale* of his patients, endeavoring gradually to accustom them to the idea of the operation, allowing them, whenever it be possible, to name the day, always securing them from pain by the use of chloroform, etc. He is also careful to remove the patient as far as possible from cases of erysipelas, etc., which, unfortunately at La Pitié, cannot always be very far. After the operation, he is especially careful to avoid doing anything to cause pain. Never places any apparatus on the stump which will render it necessary to lower or raise it; does not attempt to draw together the edges of the wound, and rejects the use of alcohol in the dressing to avoid pain; places the patients on a mechanical bed, which allows them to be moved without suffering. By these precautions, out of 48 amputations he succeeded in saving 29 patients, a mortality of 39 on 100. Of the 19 deaths, 10 only were by purulent infection.

As an instance of the disastrous influence of moral shock, M. Gosselin cites the case of a patient who was doing well, when he heard that his wife had become insane and was at the Salpetrière. Very soon afterward he began to shiver, and fell a victim to purulent infection.

M. Verneuil, the distinguished surgeon at Laribosisière, especially occupied himself with the consideration of the previous health of the patient. The influence of diseases, manifest or latent, of the kidneys and lungs, of drunkenness, miasm, etc., is constantly proved by the unfortunate results of the best conducted operations. M. Verneuil thinks that erysipelas more frequently occurs in individuals with the herpetic or arthritic diathesis.

M. Labat attached less importance to previous or coincident diseases, and agreed with M. Bourgade in the attention needed for the local conditions of the wound. He lays down several rules as follows:

1. Never attempt to obtain immediate union except when the wound is shallow, the texture of the tissues uniform, the opposed surfaces can be maintained in contact as well as the edges, and the tissues have not been too profoundly bruised.

2. Carefully avoid all conditions which may lead to the alteration of the fluids, and their sojourn near the mouths of the veins.

3. Favor the draining of fluids by a tube or other means, establishing a canal from one end of the wound to the other.

4. Avoid the employment of all irritating substances, especially in regions abundantly provided with lymphatics.

5. In anfractuous wounds, fill up the anfractuosities with lint, so as to avoid the accumulation of fluids.

6. Preserve the limb as immovable as possible, and avoid too frequent dressings.

7. Abstain absolutely from the application of pure water on the wound; always use alcohol.

8. Whenever there is reason to fear purulent absorption, give ergotine in the dose of two to three grammes from the first day, and continue as long as the danger lasts, usually ten or twelve days.

A distinguished professor from Rome, M. Mazzoni, pointed out the necessity of isolating the surgical wards from those containing fever or tuberculous patients, a precaution hardly ever adopted in French hospitals; but at Naples, Professor Palasciano did not hesitate to

tender his resignation when the attempt was made to approach a fever ward near that of his operated patients. M. Mazzoni asserted the comparative immunity of the Italian hospitals, even the maternities, from erysipelas and puerperal fever, in all cases except where the usual precautions to exclude patients affected with fevers or other contagious diseases, or with tuberculosis, are for some reason neglected.

Mr. Meric, of London, also claimed for the English hospitals the merit of great attention to this point, and ascribed to it much of the superior success of English surgeons in ovariotomy.

But sometimes the most lively debates of the entire Congress were excited by the question of syphilis, and its means of prevention by legal measures. With the exception of Dr. Drysdale of London, and one other physician who wished to oppose moral education to the extension of the frightful evil, it was everywhere assumed that the only efficacious measures consisted in strict surveillance over prostitutes. In proof of the results obtained by this means, several members read elaborate memoirs. The first was sent by M. Wleminckx of Brussels, who pronounces that to be the best regulated of cities in this respect. All the registered public women are examined every three days, and punished if they fail to present themselves for examination. Upon the slightest suspicion of disease they are sent to the hospital. All physicians are forbidden to treat prostitutes at their houses. Rewards are offered to such women as present themselves regularly for examination. By means of these precautions, M. Wleminckx asserts that the number of syphilitic diseases has very considerably abated, and secondary and tertiary affections have nearly disappeared.

In addition to these measures applied to women, in military hospitals all syphilitic patients are rewarded if they will denounce the person from whom they have contracted the disease.

M. Crocq, also from Belgium, observed that these measures, so efficacious in the great cities, were neglected in small villages, which served as places of refuge for clandestine prostitution, and were indestructible foci of syphilis.

M. Rollet, in the name of the Imperial Society of Medicine at Lyons, advocated not only surveillance of the women, but of all men in situations where their conduct could be controlled, as soldiers, sailors, etc. In view especially of the terrible accidents recently occurring at a large glass factory, where the workmen being compelled to apply their mouths successively to the same tube, nearly all contracted the disease from one whose mouth was the seat of syphilitic ulceration, M. Rollet recommends the extension of this surveillance to the glass-blowers also.

M. Buchon made a report of the measures actually enforced in the French navy. Every sailor or soldier is submitted to an examination, previously to the arrival of the vessel in port, and none are permitted to go on shore without a certificate of perfect health. Same precautions before leaves of absence are granted. Thanks to this incessant surveillance, which although of ancient date has been especially vigorous since 1830, the navy department has greatly diminished the number of syphilitic patients admitted into the hospitals. At Brest, where the hospital formerly always contained three hundred beds of such patients, the number has diminished to one hundred.

M. Le Fort presented some statistics concerning the actual state of prostitution in Paris. The total number of registered prostitutes is 3,851, of which 1,306 are distributed among one hundred and sixty-five houses —the rest are isolated. The amount of clandestine prostitution is enormous, but cannot be estimated. All soldiers treated for the disease are compelled to reveal its source, and the police pursue the woman. A certain number of girls are arrested every day for clandestine prostitution; among 13,818 of this category, 3,728 were found to be diseased, 1,131 were sent to St. Lazare, 7,217 reclaimed as minors by their families (!), 1,549 only were registered.

In six years, 504,000 examinations have been made with the speculum upon prostitutes, and 3,720 contagious diseases have been thus discovered. This number is small in comparison to the number of examinations, but considerable in proportion to the number of prostitutes registered.

In spite of all this surveillance, as Mr. Drysdale of London remarked, syphilis is not less frequent in Paris than London, where prostitution receives no sanction from authoritative surveillance.

The question that really excited the Congress almost to a flame, was that of the possibility of preventing syphilis by inoculation. It is unnecessary to record the debate in which M. Ricord quite overbore M. Auzias-Turenne, who enthusiastically advocated such inoculation. Several very disastrous and even fatal diseases were reported by those who adhered to Ricord's doctrine, as the consequence of inoculation with the hard chancre. The discussion had no especial result.

Complementary sessions were held from time to time in the evening, in which various interesting subjects were suggested or debated. I have already overpassed my space, but must mention two communications of real curiosity.

The first is the exposition, by M. Brunetti, of a new method for preserving anatomical pieces. His preparations have been on exhibition at the Exposition, but the process hitherto has been kept secret. In an evening session, however, M. Brunetti revealed it; and, as I know from personal examination of his preparations, the results are so admirable, that every one should be acquainted with the method.

Several operations are included; the washing of the piece, freeing it from fat, its tanning and desiccation.

To wash the piece, M. Brunetti passes a current of pure water through the blood-vessels and excreting canals; then alcohol to expel the water.

Then ether is made to replace the alcohol in order to dissolve the fat; this process requires several hours. The ether penetrates everywhere, and everywhere accomplishes its work thoroughly. At this point, the piece plunged in ether can be preserved indefinitely before proceeding to further operations.

Then tannin is dissolved in boiling distilled water, and this solution is passed into the blood-vessels, etc., after the ether has been driven out by a current of distilled water.

Then the piece is dried by being placed in a vase with a double bottom, and containing between the two, boiling-water. By means of a reservoir where the air is compressed to about two atmospheres, and which communicates by a stopcock and a system of tubes, first with a vessel containing chloride of lime, then with another empty and heated, then with the vessels and excreting canals of the piece, M. Brunetti establishes a gaseous current which expels all the liquids. The operation is then finished, and the piece remains supple, light, with its natural size and relations, and all its solid histological elements. The most perfect microscopic slices may be made from the preparation.

The other invention, which is too good, or at least too striking, to be passed by in silence, is an instrument for *Somatoscopy*. This was presented by M. Millot, of Russia, and is designed to illuminate the cavities of the

body, so as to render them transparent to the eye. The apparatus is composed of a glass tube containing a platinum wire curled up on itself, and communicating by copper stems with the two poles of an electric battery. When the current is passed, the platinum wire grows glowing white, and emits an intense light. This tube introduced into the stomach, vagina, or rectum of the cadaver, has enabled the observer to see by transparence the walls of the abdomen. M. Millot made some experiments upon animals before the Congress, but so far he has had no opportunity to test his apparatus on the living subject. He hopes, however, by its means to bring great assistance to the diagnosis of tumors of the ovary, and even adherences, and also of calculi and tumors of the bladder. P. C. M.

THE ADMINISTRATION OF CHLOROFORM BY THE VAPORIZER.

To the Editor of the Medical Record.

Sir—Permit me respectfully to submit to the consideration of your readers a few remarks on chloroform, and a new method of administering it as an anæsthetic.

The ordinary way of giving chloroform as an anæsthetic is objectionable on account of the deleterious effects of the carbonized air formed within the inhaler by the respiration of the patient. An absorption of the carbonic acid gas into the system, either alone or with chloroform, causes various degrees of toxicological effects. These do not always depend on the quantity of the poison thus taken; but are much owing to the condition the poison finds, that *nerve power* which ever shows its resistance to all agents that are enemies to the integrity of the body. In this toxico-physiological struggle, so to speak, either the one or the other will triumph, resulting either in the death or recovery of the patient. If our premises are correct, we have a clue of the causes of death from the effects of chloroform, in cases where no known disease exist in the patient, that are considered incompatible with the condition of chloroformic anæsthesia.

To lessen danger in giving chloroform by inhalation, I have lately used the spray in such a way that the vapor is received into the lungs highly oxygenated with atmospheric air. This is accomplished by the use of an elastic air-pump, attached to a dental spray instrument. The spray of chloroform is forced into an inhaler, which is a cone made of a towel, giving it firmness, and in a measure making it impermeable to vapor by pinning several layers of writing-paper around it. The inhaler with this arrangement is put over the patient's nose and mouth, and as the spray is pumped into it, it is received by inhalation. The action of the spray may correspond to each inspiration of the lungs. By this method of administering chloroform but little is required, and its effects are highly satisfactory. I am firmly impressed with the belief, that this mode of etherizing patients is accompanied with no more danger than there is in the use of the nitrous oxide gas.

On the 13th day of August, 1867, I extirpated, at Coxsackie, New York, a mammary cancerous tumor from Miss E. J. S. My assistants were Drs. Williams, Spoor, and Jackson. The patient was of plethoric habit, and was prepared for the operation by aperients and low diet. Twenty minutes before administering the spray we gave her an ounce of brandy. The anæsthetic given in the case was a mixture of equal parts of chloroform and sulphuric ether. The patient, in a few minutes, was gradually and promptly brought under its full influence. The operation was completed, and Sims' sutures inserted as the patient merged into consciousness. The amount of chloroform used in this case was one teaspoonful, or one tablespoonful of the mixture. The effects of the anæsthesia were of short duration, and the wound healed almost by the first intention.

Hudson, N. Y., Sept. 16, 1867.

THE LIQUOR ZINCI CHLORIDI IN GONORRHŒA.

To the Editor of the Medical Record.

Dear Sir—My attention was called this morning to the following paragraph in Dr. Bumstead's work on venereal diseases: "The chloride of zinc is a powerful caustic and irritant, which fulfils, although in a much less perfect manner, the same indications as nitrate of silver, and may, therefore, be used under similar circumstances." "It is a favorite injection with some practitioners, especially with my venerable friend Dr. J. P. Batchelder, who employs a very strong solution in all stages of gonorrhœa, and states that but few cases resist more than a week. Dr. B. dissolves 3 ij of the chloride in 3 iij of water, and directs the patient to commence with three drops of the mixture to a tablespoonful of water, and inject three times a day; to add a drop at a time (rarely exceeding eight drops) until a smarting sensation is produced, and then gradually to diminish the strength until the discharge disappears." This paragraph contains a most singular mistake or misunderstanding in regard to my use of the chloride of zinc in gonorrhœa. I do not in fact recollect ever having prescribed it in any case whatever, except as a caustic in cancerous affections. My injection in gonorrhœa is simply six drops of the liquor zinci chloridi to an ounce of water—the injection to be made three times a day, the strength of the injection to be regulated by the effect produced, a slight uneasiness only being desirable. The discharge usually disappears in the course of three or four days. I generally, however, advise the patient to inject cold water as he did the injection proper for several days. The cure is usually accomplished in five or six days from the commencement of the treatment; and I may add that patients treated in this way are rarely affected with chordee, and seldom require any internal remedy.

J. P. Batchelder.

New York, Sept. 26, 1867.

THE DISCOVERER OF ANÆSTHESIA.

To the Editor of the Medical Record.

Sir—A recent article in the Medical Record, on the discoverer of anæsthesia, does not seem to me to reach the true point at issue; and much of the discussion of the respective claims of Drs Morton, Wells, and Jackson, is irrelevant, from failure to understand just what those claims are. Knowing Dr. Morton well, and what he does claim, from personal conversation, I ask your indulgence of a limited space in reply.

Dr. Morton does not claim to be the discoverer of sulphuric ether, or of the principle of anæsthesia—nor does Dr. Wells. Local and general anæsthesia (*ana* without, and *aisthesis*, feeling, or consciousness), has been known for centuries, and signifies in its professional application a condition in which operations may be borne without pain or consciousness of suffering; it refers to a class of agents by which pain is relieved, and susceptibility to it suspended; thus opium and other narcotics, cold locally applied or in its general effects, alcohol to the extent of complete insensibility, have all been long employed for anæsthetic purposes.

nitrous oxide gas was long known to the profession, and its peculiar properties vaguely understood; but it is granted by all familiar with the discussion, that Dr. Wells was the first to make a practical application of its *anæsthetic property* in the extraction of teeth—and the honor let none take from him—but here he stops; a hint, taken from the accidental injury of Mr. Cooley while under its influence, suggests the idea of extracting teeth without pain; the experiment succeeds, and since then has been constantly employed. This is not the *discovery* of nitrous oxide—nor is it the discovery of anæsthesia! Mr. Colton employed it long before—it is the practical application of the gas, as a feasible agent, by means of which teeth may be extracted without pain; beyond that it has never been carried. Its effects are too fugitive to admit of severe surgical operations under its influence; here was the fault—and here Dr. Morton introduces sulphuric ether, having tried it upon himself and others, claiming for it what could not be claimed for nitrous oxide gas, or any other known agent, the power of inducing insensibility long enough to admit of severe surgical manipulations.

Dr. Wells did not discover nitrous oxide—but he did conceive the idea of its employment as an anæsthetic. Dr. Morton did not discover sulphuric ether—but he did discover, by long experimentation, properties which others knew nothing of, and giving them to the world, became one of its grand benefactors.

Great discoveries are not stumbled upon often; patient thought, long and close investigation and experiment, are the price of any really valuable advance in science or art. Obstacles constantly present themselves, and deter many. It is only he who has greater faith, and, seeing the clue, follows it out in all its intricacies to the ultimate result, who is the victor. Hints are caught from others unconscious of their value; but to the patient investigator they are as parts wanting in a chain, and seen, are at once seized and worked in in their own proper place, and lo! the chain of induction is complete. Now, what was wanted previous to the discovery claimed by Dr. Morton was, an agent safe in its effects, and which would suspend consciousness long enough to admit of surgical operations. Did nitrous oxide gas meet this want? It was simply an advance by which trivial operations could be performed. It is asserted that Dr. Morton previously obtained whatever he knew of the practicability of anæsthesia from Dr. Wells. Dr. Morton denies this; but grant it as relating to anæsthesia by nitrous oxide, did Dr. Wells originate or develop the principle? It was known long before; and if it is said by way of detraction from Dr. M. that he owes the idea to Dr. Wells, just as true is it that *he* owes the idea to the accidental administration of the gas in his presence. The test of the real value of an article is its practical application to real wants. The gas never met them, and has never been claimed as really valuable in general surgery. Franklin drew the lightning from the clouds—is he entitled to the credit of the discovery of the electric telegraph? No more is Dr. Wells to the honor of this magnificent discovery. Recognizing a want never yet met; grasping isolated facts and arranging them in their proper relations; seizing hints here and there, by patient thought and bold experiment, Dr. Morton announced to the world the discovery of anæsthesia by an agent harmless in its proper careful use, and adapted to the wants of the surgeon. Struggling against incredulity and prejudice, he forced it upon obstinate unbelief; he combatted dogmatic opposition in this country and in Europe from the profession, the pulpit, and the press; and at last, when a reluctant assent was given to its worth, and this changed into grand eulogy of its immense value, his claim is for the first time disputed. The "Report" of Hon. Truman Smith is easily explained when it is understood that he is trustee for the Wells estate, and so is rather a special plea than an impartial scientific document. Scarcely a medical society in this country but has already accorded to Dr. Morton the honor which he claims; and while perhaps, at this late day, no new facts may be adduced, yet a careful consideration of those already presented can scarcely fail to establish his claim in the minds of the profession throughout the country.

I am, sir, truly yours,

J. W. LAWTON, M.D.

SYRACUSE, N.Y., Sept. 4, 1867.

A CASE OF ELEPHANTIASIS ARABUM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—As cases of *Lymphangitis Chronica*, or *Elephantiasis Arabum*, are proverbially rare, particularly among the German element of our population; and as the subjoined case presents one or two points of interest, the same is respectfully tendered for publication:

Catherine M——, aged forty-three years, wife of a street-sweeper, presented herself on the 19th of June, 1866, at the surgical department of the German Dispensary. Her frame seemed fragile, her countenance cadaverous; when, upon being questioned regarding her malady, two legs of enormous proportions were exhibited, the left one especially being huge and unwieldy.

The disease commenced, without any assignable cause, twelve years ago. Its growth was slow, but steady, for two years, when an invasion of the tissues of the right leg commenced. After the lapse of four years from the first manifestations of the disease, it remained stationary. The following appearance was then presented:

From knee to ankle-joint a smooth mass of tissue, divided into three large swellings, or tumors, separated by excoriations and fissures. On the outer circumference of the first tumor was a flat, granulating sore, which, however, was gangrenous posteriorly.

The dimensions were as follows: circumference at knee, 12½ inches; at knee, above patella, 14¾ inches; of the first tumor, 25 inches; of the second, located at the middle third of the tibia, 24 inches; of the third, near the ankle-joint, 15 inches.

Difficulty of locomotion, and consequent abstinence from many enjoyments, were the only inconveniences for a long period.

During the month of November however, erysipelas, with subsequent ulcerations, and several profuse hæmorrhages occurred, the latter having caused the debilitated condition already mentioned.

As the results which are obtained through operative proceedings are very unfavorable, and as her anæmic cachectic condition contra-indicated any surgical procedure, recourse was had to the *expectant method*.

Accordingly, Dr. L. Voss, who then officiated, directed the gangrenous sore to be dressed with a solution of permanganate of potassa, and exhibited large doses of iron internally.

These, with absolute rest, horizontal posture of both limbs, methodical compression, and the most nutritious diet, constituted the course of treatment.

In March, 1867, she reappeared at the Dispensary, when a few folds of hypertrophied skin were the only remaining traces of a former hideous disease.

Yours truly, DAVID BREKES, M.D.

NEW YORK, Sept. 23, 1867.

THE RUSH MEDICAL COLLEGE, CHICAGO.

To the Editor of the Medical Record.

Sir—Yesterday was a proud day in the annals of medicine. The twenty-fifth annual course of lectures by the Faculty of Rush Medical College was opened in the splendid edifice which has just been completed for the institution. The lower lecture-room was crowded by the alumni, the students, and members of the profession, who were assembled at eight o'clock in the evening, to hear the introductory address. It was the largest gathering of medical men that has ever been seen in the Western States. Upon the platform were the members of the Faculty, the Mayor of the city, and a number of distinguished citizens. One only who should have been present, was invisible—the founder of the college, the famous teacher whom envious death had snatched too early from the scene of his triumphs.

After the usual formal prayer and discourse of sweet music, the President of the College, Prof. Blaney, pronounced an inaugural address, which had for its subject, "The past History of Rush Medical College."

These interesting reminiscences were followed with an appropriate speech of congratulation by the Hon. J. B. Rice, Mayor of the city. The new professor of surgery, Moses Gunn, M.D., was then introduced to the audience, and proceeded to open the course of lectures with an address well calculated to excite the attention and the attachment of his future auditors. After this conclusion of the literary exercises of the evening, Professor Blaney invited the guests of the school to an entertainment which was served in the spacious dissecting-room. Everything was conducted with perfect good taste, and there was nothing that could mar the harmony of an occasion which can never be forgotten by the delighted assembly.

Rush Medical College has now attained its majority. Possessing the finest building in the United States, its exterior attractions alone are sufficient to insure permanent prosperity. The new structure, which was last night so happily dedicated, is built of brick, with an interior facing of white concrete instead of plaster. It has a front of sixty feet on Dearborn street, by seventy-two on Indiana street, and its height is sixty-six feet. The old building, which measures thirty-two feet by seventy, is immediately adjoining, and communicates with the new. In this edifice are the chemical laboratory and the dissecting-room. The lecture-rooms fill the whole length and breadth of the new building. The lower lecture-room presents an appearance similar to that of the amphitheatre of the College of Physicians and Surgeons, N. Y. It is, however, much larger, and the semicircular tiers of seats rise upon the *panoptic* curve —a great improvement. The ceiling is supported at an elevation of twenty-six feet, by four massive iron pillars. Light and air are freely admitted through windows which pierce three of the walls at the level of the highest row of seats. Above this splendid room is the anatomical theatre, with its seats for seven hundred students. Lighted through the dome from an elevation of fifty feet above the professorial arena, the dim vastness of its depths, as seen last evening, was well calculated to create a profound impression upon the minds of the students who, for the first time, were entering the precincts of *Alma Mater*. Besides these spacious theatres, the building contains a quiz-room, sixteen feet by thirty; the dissecting-room, thirty-eight feet by eighty; a museum, a laboratory, rooms for the professors, a dispensary, the hall of the College of Pharmacy, a hospital ward, the janitor's room, and a cellar for the preparation of anatomical subjects. The edifice is heated by steam, and contains, as we are told, every appliance to make it the most perfect medical college building in the world. All this upon a site which forty years ago was a howling Indian camp-ground. It is wonderful!

M.

Medical Items and News.

PERSONAL.

Dr Adam Frank, of Philadelphia, has been appointed an assistant surgeon in the navy.

Surgeon James McClelan has been ordered to the naval rendezvous at Philadelphia.

Surgeon C. S. Clebourne has been ordered to the apprentice-ship Saratoga.

Drs. Frank H. Hamilton, Elisha Harris, T. Gaillard Thomas, Theodore Walser, and A. Nelson Bell, have been appointed the Executive Committee at a recent meeting of physicians, and have in charge matters relating to the relief of the Southern yellow-fever sufferers.

Goodyear versus the Dental Vulcanite Company.—An important patent case in Baltimore, of Goodyear against the Dental Vulcanite Company, which was argued last spring, has just been decided in favor of Goodyear.

New Works.—Prof. Geo. T. Elliot, of this city, is engaged upon a work on Clinical Obstetrics, to be issued shortly by the Appletons; and Prof. C. A. Lee, of Peekskill, New York, is similarly occupied with a work on Practical Therapeutics.

N. Y. County Medical Society.—At the anniversary meeting, held October 7th, the following officers were elected for the ensuing year: Dr. E. R. Peaslee, President; John T. Kennedy, Vice-President; Ellsworth Eliot, Secretary; and Wm. B. Bibbins, Treasurer.

The late Dr. Charles E. Morgan.—At a meeting of the Physicians and Surgeons of the Northern Dispensary, convened on Tuesday evening, Aug. 6, 1867, to

express their sentiments upon the sudden death of their esteemed and beloved associate, Dr. Charles E. Morgan, the following preamble and resolutions were unanimously adopted:

Whereas, It has pleased Almighty God to remove from our midst an intelligent, earnest, and Christian gentleman; therefore,

Resolved, That as physicians of this institution we feel the loss of one of the most worthy, efficient, and brilliant members of its medical staff; as his associates, we feel that one is lost to us whose talents, rare medical attainments, habits of patient study, and earnest devotion to his profession, gave promise of a most brilliant and successful career; as friends, we sorrow that we shall no more on earth associate with one whose many good qualities had endeared him to us all.

Resolved, That we will ever cherish his memory, and emulate his example.

Resolved, That a copy of these resolutions be sent to the family of the deceased as an evidence of our sincere, heartfelt sympathy in their deep affliction, and that they be published in the Medical Record, and the *New York Daily Times*.

Everardus B. Warner, M.D.,
Saml. B. Ward, M.D.,
B. F. Dawson, M.D.,
Committee.

(We regret to say that the above preamble and resolutions were sent to us at such a late date, that we have been unable to find a place for them before.—[*Ed.*]

Medical Society of Hudson County, New Jersey.—The regular monthly meeting of this society was held at Jersey City, September 5th. Eight members were present.

On motion, the Chairman appointed a committee of three members to take into consideration the laws of the State regulating the practice of medicine, and inquire whether any statute exists for the protection of the public against ignorant pretenders and unqualified practitioners of medicine and surgery.

The Secretary was requested to have notices of meetings published in the Jersey City and Hoboken papers, and send a synopsis of the proceedings of each meeting to the editors of the Medical Record of New York, and the *Medical and Surgical Reporter* of Philadelphia. E. W. Buck, M.D., Secretary.

The Late Dr. Taggart.—At a special meeting of the Hudson County Medical Society, held at the office of Dr. Varick, in Jersey City, on the 16th inst., the following resolutions were adopted:

Whereas, It has pleased Almighty God to remove from our midst our worthy brother, Dr. Charles Taggart, who for many years was associated with us a member of our Society, therefore be it

Resolved, That this mournful event has deprived us of one whose honorable and generous character had won our esteem, and that while we mourn our loss, we bow in humble submission to the will of God.

Resolved, That a copy of these resolutions be published in the Medical Record of New York, the *Medical and Surgical Reporter* of Philadelphia, and the papers of Jersey City.

T. R. Varick, M.D.,
E. W. Buck, M.D.,
M. A. Miller, M.D.,
Committee.

The Yellow Fever in 1853 and 1867.—The yellow fever in 1853 gradually increased from the week ending July 25 until the week ending August 25, when the deaths ran up from 21 to 1,614. The next week, ending August 28, the number of deaths by yellow fever was 1,486, and the decline then was gradual, until the disease was declared no longer epidemic on the 13th of October. The greatest number of yellow fever deaths then in any one day was 315, August 21. In 1867 the disease has certainly assumed a much milder form. Taken in its earliest stages, and promptly, judiciously, and carefully treated, a great majority of the patients recover. The number of deaths for the week ending August 31 was 126. The number for the week ending yesterday morning was 212. The highest number in any one day this year is 44. The next day the deaths declined to 30, and yesterday increased again to 43. The disease has, we believe, reached its climax. It will, we have no doubt, gradually recede from this time to the close of the season. The lesson of the yellow fever deaths this year should be engraven deeply on the public mind. It is chiefly owing to the neglect of such thorough and effective sanitary measures as were adopted by General Butler in 1862. The late city government shamefully neglected their duty to protect the public health. They embarrassed the city finances to such an extent that the present city administration is crippled, and unable to do what ought to be done to cleanse the city. The canals are abominably filthy, the draining machines are nearly worthless, the contractors to keep the streets clean neglected their duty, and hence the result. There would have been no yellow fever deaths, or but few, if prudence had been regarded in the sanitary management of the city.—*N. O. Republican.*

A Move in the Right Direction.—At a recent meeting of the Presbytery of Troy, held in Glen's Falls, New York, Elder John Lambert, M.D., of Salem, offered the following preamble and resolutions, which, after free discussion, were passed unanimously:

Whereas, It appears, from recent publications by some of the most distinguished physicians and statisticians of our country, and from articles in both religious and secular papers, that the prevention and destruction of human life is one of the common sins of our age and country; and whereas many of our leading journals are in the habit of giving a prominent place to advertisements proposing to assist in committing such crimes; therefore

Resolved, 1. That this Presbytery express their decided conviction of the great criminality of such proceedings, and of all other means contributing to like fearful results.

2. That our Church members, and the families connected with us, should avoid patronizing and encouraging journals that admit these immoral advertisements to their columns.

New York Medical Gazette.—The two first numbers of this new weekly are very creditably made up, the articles being as varied and as lengthy as the size of the journal will admit. The editorial management has been confided to Leroy Milton Yale, M.D., who will doubtless be found to be the right man in the right place, and will, with his well-known energy coupled with his literary ability, do everything to make the journal attractive to the general practitioner. We cordially extend to this new candidate for favor a welcome to our exchange list, and trust that it may rapidly earn for itself an enviable position in the current medical literature of our country.

The Memory of the Late Professor Trousseau is to be revered by the Parisian Academy of Medicine, by his marble bust, which it is proposed to place in their Hall. M. Lasègue has issued an appeal for funds to the pupils and friends of the eminent deceased, for the purpose of carrying out this object.

Original Communications.

INTRA-LARYNGEAL SURGERY.

By J. SOLIS COHEN, M.D.,

OF PHILADELPHIA.

No. III.

THE EMPLOYMENT OF SOLUTIONS IN THE FORM OF NEBULA OR SPRAY.

In the topical treatment of affections of the throat and upper air-passages, applications are sometimes requisite which shall produce more prolonged contact with the diseased structures than the local applications already described; sometimes as the chief mode of treatment, sometimes as an adjuvant to other local treatment, and sometimes for the purpose of allaying the pain of disease, or the pain produced by other local applications. The method most fully accomplishing this purpose is the employment of solutions broken up into a finely diffused spray or nebula, projected upon the parts, or directed there by means of the voluntary inspiratory effort of the patient. The principles involved in the production of the nebula, it is presumed, are familiar to the readers of the MEDICAL RECORD, and need not, therefore, be submitted to explanation here. A number of instruments employed for the purpose are depicted and described at pages 169 and 170 in Vol. I. of this Journal, to which the reader is referred. The form most frequently employed, and this on account of its low price and facility of manipulation, is the Bergson apparatus with the hand bellows of Dr. Andrew Clarke, of London (Fig. 5, Vol I., p. 170). The spray from this instrument is propelled with a considerable degree of force, and it is therefore more particularly applicable to employment in affections of the nares, mouth, pharynx, epiglottis, and upper portions of the larynx; and but little effort of inspiration beyond that of ordinary breathing is necessary to produce the effect of drawing the current in upon the diseased surfaces. When the nebula is to be made to pass the glottis, the instrument of Mathieu (Fig. 1, p. 169, Vol. I.) is much more suitable, as the spray from it is more diffused, the particles being merely suspended in the air, and therefore more apt to be carried inward by the current of inspiration. These instruments must either be set in action by the patient or by an attendant, and the pumping soon becomes irksome, so that they can be employed only for a few minutes without inducing fatigue; their usefulness thus becoming impaired to a certain degree. When, therefore, a rather prolonged application is required, it will be found more convenient to employ an apparatus in which the steam from boiling water is employed as the nebulizing force, instead of compressed air as in the instruments just referred to. Siegle's apparatus, or any of its modifications, answers the purpose of preventing fatigue, because the nebu ization is produced without muscular effort on the part of the patient or his assistant, and can therefore be kept up for as long a period as may be desirable. The trifling amount of steam which becomes mingled with the spray, can hardly dilute it injuriously, and will sometimes be of great advantage by raising the temperature of the spray. With an apparatus working by compressed air, the temperature of the nebula will be cold, unless a solution in hot water be employed, or the apparatus, at the moment of its employment, be placed in a vessel containing warm water. Steam apparatuses of this kind are depicted in figures 3 and 4, page 170, of Vol. I. In most of the various modifications of Siegle's steam hydrokomion, as also in the original instrument as invented by him, the horizontal tube from which the steam emerges is bent before entering the boiler, so as to dip down into it from above; and in using these we find, every now and then, especially soon after the apparatus is set in action, that the steam condenses at this elbow in the horizontal tube, and as this is driven forward by the escape of the steam still forming behind it, it spurts out the hot water with some force, sometimes projecting it into the face or eyes of a patient with very uncomfortable results, and occasionally creating an indisposition to further continuance of the process. This can in great measure be avoided by having the horizontal tube pass directly into the boiler from the side, close to the top, and thus avoiding the curve which the steam strikes in its ascent. The ascending steam now strikes the top of the boiler, and condenses there without impeding the escape through the horizontal tube of the apparatus. This is the form of instrument that the writer is in the

habit of employing; with tubes of a duck-bill form, which permits of their being introduced within a mouth speculum, and thus avoiding considerable loss of spray. The tube passes into the boiler through a cork, which would readily be blown out by an excess of steam, thus doing away with the necessity for any special safety-valve to prevent explosion of the boiler. With this modification, the apparatus, as depicted in the above figure, is essentially the apparatus of Siegle, having his original arrangement of a lamp with a screw for raising and lowering the wick so as to regulate the evolution of the steam. A small lamp beneath the medicine glass can be used to heat the solution, when desirable to increase the temperature of the nebula. A mouth speculum is used to protect the teeth, tongue, roof of the mouth, etc.; and the tube entering the funnel extremity of the speculum, the face and clothing are thereby protected from the spray, a very desirable precaution in the administration of solutions containing nitrate of silver, or other discoloring articles. The condensed fluid, as it flows out of the funnel extremity of the speculum, can be directed into an appropriate receptacle so as to protect the clothing and furniture. The instrument, with all its appurtenances, can be obtained from Mr. GEMRIG, the prominent surgical-instrument maker of Philadelphia.

Any article of the materia medica, soluble in water, or in weak alcohol, is suitable for employment by this process. Oils, and solutions in glycerine have also been employed, but in such cases the apertures of the distributing tubes must be larger than suffice for

watery or alcoholic solutions. This method is much superior to that of gargles, because, by the minute subdivision of the particles of the fluid, and their divergence in exit, more complete contact with the structures is secured, as well as a more continuous effect. Their superiority to gargles is readily shown, for it is impossible to gargle in such a manner that the fluid shall come in contact with the posterior wall of the pharynx without a voluntary attempt at swallowing at the moment of gargling, which, at the best, but secures an imperfect and limited contact. One can prove this by gargling with some colored solution, such as of indigo or aniline, and then examining the effect before a looking-glass. He will find the roof of the mouth, tongue, and soft palate covered with the color employed, but not the deeper structures. Besides, in those diseases accompanied with acute inflammation of the fauces and pharynx, gargling is often impracticable on account of the pain produced by the effort, and sometimes on account of the difficulty of opening the mouth to a sufficient extent. With the nebulizer, however, we can direct the spray into the mouth when it cannot be widely opened, and secure contact of the solution with the affected surfaces without any other coöperation on the part of the patient, than such as simply opening his mouth to prevent the ingress of the spray.

These applications may be used in many affections of the throat and upper air-passages. In *coryza*, the spray can be readily inspired into the nostrils by simply giving the head a suitable inclination. The remedies which have been found most applicable to this disease are muriate of ammonia, to induce free secretion in dry snuffles, and alum to repress the profuse discharge of rhinorrhœa, as also, by its antiseptic qualities, to counteract fetor when present.

In *acute inflammations of the pharynx and fauces*, remedies applied in this manner are of great value. Alum and tannin are the articles most frequently employed; alum, perhaps, being indicated in the greater number of instances. The solution of alum may vary in strength, from five to twenty grains to the ounce of water, and may be employed frequently during the day. When much pain is present, some narcotic, as the extract of opium, from a quarter of a grain to a grain, may be advantageously added to the ounce of the solution of alum. Recent inflammations of the tonsils, especially in persons subject to frequent attacks of tonsilitis, can sometimes be rapidly subdued by the application of a nebulized solution of alum, five or ten grains to the ounce of water, repeated every hour or two hours until the desired effect has been produced. Sulphate of copper, in the proportion of from five to twenty grains to the ounce, has been used with similar results.

In the acute inflammation of these structures accompanying the exanthemata, as in the anginose variety of scarlet fever, we have in these applications an admirable method of affording relief to local suffering, moderating the degree of inflammation, and cleansing the parts of accumulating exudation.

In the exudations accompanying diphtheria and pseudo-membranous croup, we have a means of making local applications in cases where the employment of any other method would be impracticable. Strong solutions of tannin have been employed for this purpose in the St. Eugénie Hôpital des Enfants, with success; chlorate of potassa, bromide of potassium, and other remedies of this class, have been variously recommended; hot water broken up by nebulization, and breathed in upon the parts, is a most invaluable remedy; but the remedy now fashionable, and a good one it is, is the lime-water, which, as demonstrated by Küchenmeister, and confirmed by Biermer, Förster, and others, has a peculiarly solvent effect upon diphtheritic deposits which have been expectorated or detached from the mucous membrane; though it is by no means certain that this solvent effect can be depended upon while the deposit is *in situ*, for it has been demonstrated by Dr. Da Costa, in at least two instances, that the local application of lime water had no visible effect upon the diphtheritic deposits against which the spray was directed with great care by himself.

In these cases, it is not unlikely that the beneficial effects attributed solely to the lime, are in great measure due to the warm water with which it is combined, for the instructions are to administer the lime inhalations hot to secure the best results. In these and similar cases, the employment of warm water alone, apart from its soothing effect as a fomentation applied to the parts, as to an inflammation on the surface of the body, by supplying moisture, prevents, or at least retards, the congelation of the diphtheritic exudation, and in this manner conduces to facility of detachment and expectoration.

In *chronic inflammations of the pharynx and fauces*, the remedy which seems to have produced most general benefit is tannin, in the proportion of from one to ten grains to the ounce of water. In these cases the applications need not exceed two or three a day. Occasionally a weak solution of sulphate of zinc, a grain or two to two or more ounces of water, will produce a more satisfactory result than the tannin. In obstinate cases, especially when they have been of long standing, weak solutions of iodine, such as five or ten drops of the tincture, or twenty to thirty drops of Lugol's solution to the ounce of water, perseveringly continued, will gradually establish an alterant influence which will eventuate satisfactorily; especially will this be the case when there has been glandular involvement of the follicles, tonsils, or lymphatics.

There is a form of dry pharyngitis, *pharyngitis sicca*, which often causes a great deal of distress, producing attempts at clearing the throat which afford no relief, and sometimes accompanied with intolerable burning; in such cases advantage may be expected from the use of a nebulized solution of the muriate of ammonia, from two to ten grains to the ounce of water, and resorted to two or three times in the twenty-four hours.

I have seen a few cases of chronic inflammation of the fauces produced by exposure in the fire-rooms of engine works, in which the application of the spray of warm water, or a warmed infusion of wild cherry bark, has afforded a great deal of relief during the period of exposure.

Solutions of the nitrate of silver, from a quarter of a grain to a grain or two to the ounce of water, have been recommended, employed in this manner, in chronic pharyngitis.

Syphilitic angina has been successfully treated by the application of a solution of corrosive sublimate, one or two grains to the ounce of water.

In *acute laryngitis* the inhalation of a nebulized solution of distilled water, sometimes containing from two to ten grains of common salt to the ounce, has been found of great service. Alum, tannin, muriate of ammonia, sulphate of zinc, the mineral acids, have all been recommended in this complaint; with the addition of a little narcotic for the purpose of subduing pain. Warm water alone will often afford a grateful feeling of relief.

In *chronic laryngitis*, whether existing as a distinct affection, or connected with tuberculosis, alum, tannin, chlorate of potassa, the salts of iron, iodine, and weak solutions of nitrate of silver, have been recommended by various authorities. The writer's experience leads

him to prefer local applications by means of the sponge or mop, as more directly beneficial, and especially so in cases where ulceration has occurred; though the various astringent, alterative, and protective inhalations are often to be advantageously employed in addition.

In *œdema of the larynx* inhalations of a strong solution of tannin, frequently repeated, have been warmly recommended by Trousseau, who relates two cases in his *Clinique Médicale*. In two instances under the writer's care prompt relief followed the employment of an opiate solution, which, in the first case, had been administered for the purpose of subduing local distress preparatory to the employment of scarification.

In the recommendation of the above measures for the local treatment of affections of the throat and upper air-passages, it is not to be understood that general treatment, the regulation of diet, and so on, are not to receive as much attention in the management of disease as if the local measures were not resorted to. All that is claimed, and this much is claimed, is, that affections of these structures can be treated much more successfully by the employment of these methods of local medication, in addition to systemic treatment, than by reliance upon general medication alone.

A CASE OF
COMPLETE LATERAL LUXATION OF THE RADIUS AND ULNA OUTWARDS.

By THEODORE R. VARICK, M.D.,

JERSEY CITY, N. J.

Geo. Knight, æt. 9 years, was thrown violently from a wagon while in rapid motion, striking on his head and back, with his left arm behind him in a state of flexion. He was brought to my office on the 31st of August, 186*7*, within ten minutes after the receipt of the injury, and, consequently, in the most favorable condition for manipulation, no swelling of the soft parts having yet occurred. The forearm was in a state of semi-flexion, supported by the hand of the opposite side, the ulna lying to the outer side of the external condyle, with slight posterior projection of the olecranon. The olecranon, coronoid process, and greater sigmoid cavity could be distinctly defined, and the head of the radius in its normal attachment, could be felt rotating subcutaneously on pronating and supinating the forearm. Free motion of the forearm in every direction was present, giving the impression of being attached to the arm solely by the soft parts. The projection of the internal condyle was out of all proportion to what is seen in cases of incomplete luxation. The trochlea, coronoid depression, and the olecranon depression were distinctly recognized. Complete dislocation of the ulna outwards was diagnosed, which diagnosis was corroborated by my friend, Dr. B. A. Watson, who was present and assisted in the reduction.

The patient was placed fully under the influence of ether, and moderate extension, combined with lateral pressure, effected the reduction without difficulty. The subsequent treatment consisted of rest and cold irrigation for a few days, followed by passive motion of the parts, which resulted in perfect recovery. The amount of inflammation which followed the injury was exceedingly slight, due unquestionably to the prompt reduction of the luxation.

The exceeding rarity of accidents of this kind renders the case one of more than ordinary interest. So rare are they that Sir Astley Cooper doubted the possibility of their occurring, and writes as follows: "With respect to lateral luxations, they are always incomplete, and easily discovered." Gross's scepticism is expressed in the following words: "Lateral dislocation of the elbow-joint, besides being exceedingly rare, can scarcely occur in any other than an incomplete form, and as a consequence of severe injury extensively implicating the soft parts."—*System of Surgery*, vol. ii., p. 70.

Errichsen's testimony is, "complete lateral dislocation of the bones of the forearm being exceedingly rare."—*Science and Art of Surgery*, p. 254.

According to Chelius, "The lateral dislocation may be either complete or incomplete; that outwards is more frequent than that inwards."

"In complete lateral dislocation the projection of the fore and upper arm are much more decided than in the incomplete, and on account of the great tearing of the soft parts, the forearm is movable in every direction."—*System of Surgery*, vol. ii., p. 229.

Hamilton writes as follows: "The large majority of outward dislocations of the forearm are incomplete; indeed, only nine examples of a complete dislocation have been collected by Denucé, including two seen by himself. Malgaigne has since added two more, making in all eleven cases. All these examples have occurred in the practice of French surgeons. So far as I am able to discover, no American or English surgeon has ever reported a single example."—*Frac. and Dislocations*, 3d edition, p. 601.

Nelaton has also reported one, making in all thirteen recorded cases of the accident; which may be summed up as follows: Denucé, nine cases; Malgaigne, two; Nelaton, one; Varick, one; total, thirteen.

CASE OF DIABETES MELLITUS FOLLOWING INJURY OF THE BRAIN.

By DR. McCLINTOCK,

MORRIS, N. Y.

I was called, February 18, 1867, to see A. P., twenty years of age, from whom I obtained the following history: In February, 1866, while felling timber in the woods, he received a blow on the head from a falling branch. He was removed to the house, and two creditable physicians were called to attend him. They discovered a longitudinal fracture of the occipital and the parietal bones, crossing the left lambdoidal suture. The trephine was used, and a disc of bone with some spicula removed. One month later the bowels became constipated, and the flow of urine increased.

When first seen by me he was much emaciated; suffered intensely from thirst; appetite voracious; skin harsh and dry; tongue clean, red, and tender; pulse forty-eight; weight one hundred and eight pounds, showing a loss of twenty-two pounds since the injury was received. He was voiding two hundred and fifty fluid ounces of limpid urine daily, sp. gr. 1028, showing sugar by all the tests. He complained of no pain in the head or elsewhere.

The bone seemed nearly replaced; a slight open wound remained, from which oozed a drop of healthy pus. He had a little cough, which he referred to the throat or larynx.

He was placed for one month on a non-saccharine diet, with morphia, ipecac, and cod-liver oil.

At the end of this time the urine was decreased one-third, sp. gr. 1024, and the thirst and distressing symptoms much mitigated. Tinct. nuc. vom. (gtt. 45 daily) was soon added. At the end of the next month, sp. gr. had fallen to 1019, while the quantity was reduced to ninety-six fluid ounces. Bowels still very sluggish;

other symptoms much relieved; strength increased, but weight one hundred and five pounds. Treatment continued, with steam bath daily.

In August last, the cough increased with some expectoration, and, on examination, the lungs gave unequivocal evidence of tubercle, extensively diffused. From this time the course was downward. Emaciation increased, with harassing cough, œdema of extremities, and death occurred October 1st, eight months from the time I saw him, and nineteen from date of injury.

For comment, allow me to quote:

"Again, since continued irritation of the brain at the origin of the pneumogastric nerves will make the urine saccharine, the cause of diabetes in the human subject may reasonably be placed, in some instances, within the skull; and we may understand how diseases or injuries of the brain, or even mental disquiet or dejection operating through the brain, may produce it."—*See page* 1008, *Watson's Practice of Physic.*

"Bearing in mind the name and distribution of the pneumogastric nerve, may we not indulge the conjecture that disease or injury of the brain, near the origin of that nerve, may directly affect the function of the stomach, and thus prevent its digestive power—or the functions of the lungs, and thus interfere with the chemical destruction of sugar in those organs. This last notion might seem to receive support from the frequent association of disease of the lungs with saccharine urine."—*Op. cit. ante.*

Original Lectures.

LECTURES UPON THE PHYSICAL EXPLORATION OF THE ABDOMEN,

DELIVERED (OCT., 1867) IN THE PRELIMINARY COURSE AT THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF NEW YORK,

By ALFRED L. LOOMIS, M.D.,

PROFESSOR OF INSTITUTES AND PRACTICE OF MEDICINE.

Lecture I.

Introduction.—*Topography of the Abdomen—Contents of the Various Regions—Abdominal Inspection, Palpation, Percussion, and Auscultation—Diseased Conditions of the Peritoneum, Stomach, and Intestines.*

Gentlemen—There are difficulties in the physical exploration of the abdomen which are not met with in similar examinations of the thorax.

First.—Thoracic diseases involve in their diagnosis the examination of only one of two organs, or their appendages; while an abdominal affection may require for its diagnosis the examination of ten or twelve organs. Thus, a tumor on the left side of the abdomen may be either an enlarged mesenteric gland, or it may be connected with the stomach, spleen, kidneys, ovaries, or uterus; or it may be a hernia, an abscess, a hydatid cyst, an aneurism, or, lastly, only a lump of fæces.

Second.—The action of the thoracic organs is regular and rhythmical, and their contents unvarying; while the action of the abdominal viscera is often irregular and intermittent. An abdominal organ may also at one time be greatly distended with contents, and soon after be empty; when filled, its contents may be solid, fluid, or gaseous, or all these together. The lungs and heart contain respectively the same quantities of air and blood during every five minutes of ordinary life, but the stomach and bladder can never remain long in one condition, either full or empty.

Third.—The abdominal organs are packed loosely in a cavity with loose walls. They, therefore, can be increased or decreased in size so as to alter wholly their relations to their fellow organs,—thus the uterus, usually the smallest, will, in fulfilling its natural function, become much the largest of all, until it crowds even the thoracic organs; moreover, in disease a single ovary may swell into a sac which will fill entirely the abdominal cavity. These constitute the chief difficulties in the physical examination of the abdomen, and they must always throw a certain degree of doubt upon all physical diagnosis directed to this part of the body.

To facilitate our examinations, and to render our inferences more certain, it is well to divide the abdomen into regions, by passing imaginary planes through the body. The divisions which have been proposed by different observers vary somewhat. The following, which very nearly correspond to those proposed by Dr. Bright, will, I think, be found most useful:

Thus, the abdomen may be divided into three general regions—the epigastric, the umbilical, and the hypogastric.

The *epigastric* is bounded above by the diaphragm, below by a horizontal plane passing through the anterior extremities of the tenth rib on either side. In a well-formed chest the cartilage of the tenth rib on either side offers a projection at its lower convex border, which can be felt without difficulty; a horizontal plane carried backward through these points will pass between the bodies of the first and second lumbar vertebræ. This region is subdivided into the right and left hypochondria, which correspond to the spaces inclosed by the false ribs.

The *umbilical* region is bounded above by the lower boundary of the epigastric, and below by a horizontal plane passing through the anterior superior spinous processes of the ilia; this plane, if carried backward, will pass between the second and third sacral spines.

The *hypogastric* region is bounded above by the lower boundary of the umbilical region, below in the centre by the upper margin of the pubes, on either side by Poupart's ligaments. This region occupies the whole cavity of the true pelvis. The umbilical and hypogastric regions have each three subdivisions made by two vertical planes passing backwards through the spinous processes of the pubes and the points on the tenth ribs already alluded to. The subdivisions of the umbilical region thus produced are termed the central or *umbilical*, and the lateral, or the *right* and *left lumbar*. The subdivisions of the hypogastric thus produced consist of the middle or *pubic*, and the lateral, or *right* and *left inguinal.*

The organs contained in these regions in health are as follows (the situation of these organs is very perfectly shown in the diagram on page 598, Gray's Anatomy): The *epigastric* region contains the whole of the left and a part of the right lobe of the liver, the gall bladder, the pyloric orifice of the stomach, the commencement of the duodenum, a portion of the colon, the pancreas, the aorta, and the cœliac artery.

The right hypochondria contains nearly the whole of the right lobe of the liver, the angle of the ascending colon, the greater part of the duodenum, the renal capsule, and the upper portion of the right kidney.

The left hypochondria contains the rounded cardiac portion of the stomach at all times, and a very large portion of the organ when distended, the left angle of

the colon, the spleen, and a small portion of the left kidney with its renal capsule.

The umbilical region is chiefly occupied by a portion of the arch of the colon, the omentum, and the small intestines. It contains likewise the mesentery and its glands, the aorta, and the vena cava.

The right lumbar region contains the cæcum (chiefly lodged in the iliac fossæ), the ascending colon, the lower and middle portion of the kidney, and a portion of the ureter.

The left lumbar region is occupied by the descending colon, the sigmoid flexure of the colon, the left kidney, and the ureter. The small intestines likewise occupy the lumbar region on either side.

The pubic or *hypogastric* region contains in children the urinary bladder, with portions of the ureter, also in adults if they be distended, the convolutions of the small intestines, and in the female, the uterus and its appendages.

The right inguinal region contains the "cul-de-sac" of the caput coli, the vermiform process, and the iliac vessels.

The left inguinal region a part of the sigmoid flexure of the colon, and the iliac vessels of that side.

The *methods* employed in the physical examination of the abdomen, with the exception of succussion, are similar to those practised in exploration of the thorax; but they differ in their relative importance. In thoracic examinations, auscultation is the most important method, while in abdominal examinations auscultation is only employed in determining the existence of aneurisms and of pregnancy.

Percussion and *palpation* are the means by which we gain the most useful information concerning the contents of the abdominal cavity.

Before considering the signs which indicate the changes that occur in the different affections of the abdominal organs, I will briefly notice the different methods of exploration.

Inspection.—By it we note alterations in the shape and movements of the abdomen. It is most satisfactorily performed with the patient lying on the back, with the thighs slightly flexed. In health, the abdomen is of an oval form, marked by elevations and depressions corresponding to the abdominal muscles, the umbilicus, and in some degree by the form of the subjacent viscera; it is larger relatively to the size of the chest, in children than in adults, more rotund and broader inferiorly in females than in males.

Alterations in its *shape* due to *disease*, we find to consist: First, in *enlargement*, which may be general and symmetrical, as in ascites; or partial and irregular, from tumors, hypertrophy of organs, as the liver or spleen; or from tympanitic distension of portions of the intestine by gas, as of the colon in typhoid fever. Second, it may be *retracted*, as in extreme emaciation, and in several forms of cerebral disease; especially is this noticeable in the tubercular meningitis of children.

The normal movements of the abdominal walls are connected with the respiration, so that they have a certain relation to the movements of the chest walls, being often increased when the latter are arrested, and *vice versâ*. Thus, abdominal movements are increased in pleurisy, pneumonia, pericarditis, etc., but decreased or wholly suspended when disease causes abdominal pain, as in peritonitis.

Not unfrequently, when inspecting the abdomen, a distinct pulsation will be visible in the epigastric region, which frequently is mistaken for aneurism. The superficial abdominal veins are also at times visibly enlarged, indicating an obstruction to the current of blood, either in the portal system (as in cirrhosis), or in the vena cava.

Mensuration is mainly useful in determining the exact increase or decrease of abdominal dropsies, visceral enlargements, and tumors. It is performed by means of a graduated tape.

Palpation.—This method of exploration often furnishes us with the most important information. It may be performed with the tips of the fingers, with the whole hand, or with both hands, and the pressure may be slight or forcible, continuous or alternate. In order to obtain the greatest amount of information by palpation, the patient should be placed in a horizontal position, with the head slightly raised and the thighs flexed; sometimes it is necessary to place him in a standing position or leaning forward. By *palpation* we can determine the size and position of the viscera, the existence of tumors or swellings, whether they are superficial or deep, large or small, hard or soft, smooth or nodulated, movable or fixed, solid or fluid, and whether or not they possess a motion of their own. We can also ascertain if tenderness exist in any portion of the abdominal cavity, and if pain is increased or relieved by firm pressure.

In the performance of abdominal percussion, the patient should be placed in the same position as for palpation, and the percussion should be for the most part mediate. In exploring the abdomen by means of percussion, Dr. Bennett directs that the pleximeter (the finger being the best) should first be placed immediately below the xiphoid cartilage, pressed firmly down and carried along the median line towards the pubes, striking it all the way, now forcibly, now gently. The different tones which the stomach, colon, and small intestines furnish will be distinctly heard. The percussion should then be made laterally, alternately to the one side and then to the other, until the whole surface is percussed. In this manner the different percussion sounds of the stomach, large intestines, small intestines, and the solid viscera, will be readily distinguished. Thus, the percussion sound elicited over a healthy abdomen may be *dull*, *flat*, or *tympanitic*. Over the central portion of the liver, spleen, and kidneys, the percussion sound is flat; over that portion of either of these organs where they overlap the intestines or stomach it is dull, with a tympanitic quality. Over the stomach and intestines it is tympanitic, more so over the former than the latter. When fluid occupies the abdominal cavity, over the fluid the percussion sound will be flat. A distended bladder or uterus, an enlarged liver, spleen, kidney, or mesenteric gland, ovarian, aneurismal, and other tumors, are recognized and their limits determined by the unnatural and increased area of the percussion flatness; while on the other hand, gaseous distension of the stomach or intestines is recognized by the increased area of tympanitic percussion.

In the physical exploration of the abdomen, auscultation is only of service, as I have already said, in the diagnosis of aneurisms, and in detecting the pulsations of the fœtal heart, and the utero-placental murmur in the pregnant state. Our examinations of the abdominal viscera are sometimes interfered with and rendered uncertain, by changes that occur in the abdominal walls. Generally the abdominal walls are sufficiently thin, soft, and movable for us to determine with considerable accuracy the situation and condition of the subjacent organs; if, however, everything is masked by layer upon layer of fat, as in some cases of obesity, all abdominal examinations will be unsatisfactory. An œdematous condition of the abdominal walls, as in "Bright's disease," may also prevent us from ascertaining the condition of the viscera. When this occurs, the surface of the abdomen presents a smooth, even, shining, waxy appearance, and pits on firm pressure. *Superficial abscess* of the abdominal walls also occurs occasion-

ally, which interferes greatly with the exploration of the abdominal cavity. You can recognize these by the circumscribed bulging, by tenderness on slight pressure, by the redness of the surface, and by the characteristic fluctuation of a superficial abscess. The abdominal muscles also are sometimes abnormally developed, or unnaturally rigid, as in tetanus, rheumatic inflammation, and in the early stage of peritonitis; this somewhat interferes with our examinations.

DISEASED CONDITION OF THE PERITONEUM.

Under this head may be included the various results of inflammatory action, ascites, etc. They all give rise to more or less abdominal enlargement.

By *inspection* we recognize in *acute peritonitis* either a diminution or an entire suspension of abdominal respiration, the breathing becoming entirely thoracic. The abdomen enlarges, becomes unnaturally tympanitic, and there is marked tenderness on firm pressure. The comparative result of *firm* and *slight* pressure is one of the strong diagnostic marks of peritoneal inflammation.

Chronic peritonitis is almost always connected with tubercular deposits in the substance and on the free surface of the peritoneum, and in addition to the tympanitic distension of the abdomen, and the tenderness on firm pressure noticed in acute peritonitis, fluid accumulations take place in the peritoneal cavity.

Ascites is a collection of fluid from any cause in the peritoneal cavity.

On *inspection* we always find the abdomen *uniformly* enlarged, and its movements during respiration are either suspended, or limited to the epigastric region. The superficial abdominal veins, if the ascites depends upon disease of the liver, will often be found enlarged.

If the palmar surface of the hand be applied to the side of the abdomen at the level of the fluid, and light percussion be performed on the opposite side, a sense of fluctuation will be communicated to the hand.

Percussion gives flatness at the lower and most depending portion of the abdomen, while at the upper portion above the level of the fluid, there is a drum-like tympanitic resonance. When the patient is in the erect position, the tympanitic resonance is confined to the epigastrium and upper portion of the umbilical region. If in a recumbent position, the tympanitic resonance will extend into the hypogastrium; if placed on either side, the lumbar region of the opposite side becomes tympanitic. Other abnormal changes that occur in the peritoneum are connected with deposits that may be classed under the head of abdominal tumors.

In considering the physical signs which indicate *abnormal changes in the different abdominal organs*, I will commence with those of the stomach. When this viscus is empty, or not distended with gas or food, there is on *inspection* no visible prominence to indicate its position, nor does *palpation* furnish us any information as to its condition.

Percussion gives a metallic or tympanitic resonance, which enables us to distinguish it from the surrounding viscera. The line of dulness which markes the lower border of the liver, and the inner border of the spleen, determines the upper and lateral boundaries of the stomach; to ascertain the lower border, percuss gently downward from this line of dulness until a slight change in the percussion sound indicates that we have reached the transverse colon. The cardiac orifice or extremity of the organ is situated opposite the inner border of the seventh rib. At a point a little below the lower border of the liver, within a line drawn from the right nipple to the umbilicus, the pyloric orifice of the organ is situated. The lower margin of the great "cul-de-sac" is found generally near the umbilicus.

Diminution in the size of the stomach cannot be recognized by physical exploration. An increase in size or distension of the stomach may occur from an accumulation of gas, from large quantities of fluids or solids taken into the stomach, or it may be enlarged within circumscribed spaces from cancerous deposits in its walls.

Gaseous or *tympanitic* distension of the stomach is recognized by an increase in the area of the characteristic tympanitic resonance of the organ. A *distended* condition of the stomach from food or drink is recognized by an absence of the normal resonance, and by a continuation of the dull percussion of the liver and spleen downwards to the umbilicus. A moderate amount of fluid or solid in the stomach can be determined by a limited area of dulness corresponding to the normal situation of the "cul-de-sac" of the organ.

Cancer of the stomach most frequently has its seat at the pyloric extremity of the organ, but in whatever portion of the organ it may be developed it can be recognized by circumscribed dulness on percussion, where in health (when the stomach is empty) we should have tympanitic resonance. The percussion dulness elicited over the cancerous mass, however, has a hollow character which is readily distinguished from the flat percussion sound of a solid organ.

By palpation, a nodulated mass is readily detected corresponding to the area of percussion dulness, which is movable, easily grasped, and readily separated from the surrounding viscera. These signs, taken in connection with the attendant symptoms, are almost always sufficient for a positive diagnosis.

Intestines.—In a normal condition the large intestines furnish a more amphoric percussion sound than the stomach. When, however, they are filled with fluid or solid accumulations, the situation of these accumulations can be marked out on the surface by the dulness on percussion. As these most frequently collect in the descending colon, the percussion sound over this portion is usually less resonant than over the ascending or transverse colon. According to Dr. Bennett, in a practical point of view it is often useful to determine whether a purgation by the mouth or an enema is likely to open the bowels most rapidly. If there is dulness in the left iliac fossa, in the track of the descending colon, that portion of the intestine must be full of fæces, and an enema is indicated. If, on the other hand, the sound in the left iliac fossa is tympanitic, and the right dull, an enema is of little service, as it will not extend to the cæcum, and purgatives by the mouth are indicated. Sometimes the whole colon, or the transverse portion, or, what is more common, the sigmoid flexure of the large intestine, becomes distended with fæcal accumulations, giving rise to circumscribed abdominal enlargement, and to flatness on percussion over that portion of the abdomen which corresponds to the situation of the intestine. (Care must be taken not to confound this condition with an enlarged liver, spleen, tumor, etc.) The percussion sound over the small intestines, unless they are distended with gas, is higher pitched and less amphoric than that of the surrounding large intestines.

A CHOLERA MEDAL.—A decree of the King of Italy orders that a medal shall be struck in bronze, silver, and gold, to be conferred on such persons as shall have rendered signal service during the prevalence of cholera or any other grave epidemic. It will have on one side the head of the king, and on the other a crown of oak, with a legend importing that it is a recompense for services in connection with the public health.

Progress of Medical Science.

Iodine as an Injection.—Removal of the Stains produced thereby.—One of the great objections to the use of iodine as an injection being its disposition to stain the linen, Dr. Percy Boulton, of Harewood square (London), calls the attention of the profession to the fact that all such stains can be prevented by the addition of carbolic acid, which not only renders the iodine colorless, but at the same time acts as an antiseptic. He recommends the following compound: Of compound tincture of iodine, one drachm; solution of carbolic acid, six drops (as sold in the shops); water, six ounces. I have found this particularly useful, applied by means of the spray-producer to the mucous membrane of the nose in chronic ozæna, when it would have been impossible to use tincture of iodine alone in solution, owing to the staining of the face, and also of the pocket-handkerchief when used subsequently. The offensive odor in this case was at once removed, and a sense of cleanliness imparted which had not been experienced by the patient for a long time before.

Over-Eating as a Risk to Life in Operations.—Over-eating is not commonly supposed to lead to any such risks of life as over-drinking does; yet I believe that you will find in operative surgery, that among the habits that increase the risks of life, this may stand not far from drunkenness, especially if the over-eating is of meat and other nitrogenous foods. I am led to believe this from several cases that I have observed, and I think that there are large evidences of it. You know that the general results of operations in provincial hospitals tell of a smaller mortality than in the hospitals of London and the largest towns. The difference is commonly ascribed to differences in the purity of the air, and other advantages of that kind, in the comparatively rural districts. I believe that much more of it is due to the differences of habits in the several classes of patients. The differences are many; but one of the chief of them is that the poor in the agricultural districts eat far less meat than those in large towns do, and are by comparison less fed, though probably not worse fed, and you may frequently observe that patients who come to us from agricultural districts bear operations in all respects better than Londoners who are submitted to the same proceedings. Of course many things concur to make the differences of constitution between a town and a country population; but I am satisfied that among these things a very potent influence is exercised by the difference of diet; and the differences that we may thus see are strongly illustrated by what one hears of the results of operations upon the natives of India and other Eastern countries, whose diet is almost exclusively vegetable. Almost any amount of injury may be inflicted on them, and not be followed by the destructive mischiefs which occur in Europeans under the same circumstances. They are defective, it is said, in healing power; but they recover with comparative certainty, however slowly, from operations of the greatest magnitude. A common expression about them is, "You can't kill them."—James Paget, F.R.S., *London Lancet.*

A New Glycerine.—To obtain this compound M. Edmone Sichel employs four parts (by weight) of yelk of egg, and five parts of glycerine, which he mixes simply in a mortar. It has the consistence of liquid honey, and is unctuous like the fatty substances, over which it has the advantage of being easily removed by water. It is unalterable, a specimen having been left exposed to the air for three years with impunity. Applied to the skin, it forms on the surface a varnish which protects it from contact with the air. These properties render it serviceable for broken surfaces of all kinds, particularly for lumps, erysipelas, and cutaneous affections, in which it soothes the itching, and also for sore nipples: its harmlessness preventing, in the latter case, any interruption of suckling.—*Am. Jour. Pharm.*

To Prevent Pitting in Small-Pox.—Dr. C. Black (*Lancet*) claims that the complete exclusion of light from the room in which small-pox patients are confined, together with the application of hog's lard to the face to guard it from contact with the oxygen of the air, will effectually prevent pitting.

The Cause of the Activity of Animal Poisons.—Prof. *George B. Halford*, of the University of Melbourne, has discovered that in the case of the victim of the bite of the cobra di capella, molecules or living "germinal" matter are thrown into the blood and speedily grow into cells. These cells multiply so rapidly that in a few hours millions upon millions are produced at the expense of the oxygen absorbed into the blood during respiration; and hence the gradual decrease and ultimate extinction of combustion and chemical change in every other part of the body, followed by coldness, sleepiness, insensibility, slow breathing, and death. The cells which thus render in so short a time the blood unfit to support life, are circular in diameter, on the average of one seventeen-hundredth of an inch. They contain a nearly-round nucleus of one two-thousand-eight-hundredth of an inch in breadth, which, when further magnified, is seen to contain other still more minute spherules of living "germinal" matter. In addition to this, the application of magenta reveals a minute colored spot at some part of the circumference of the cell. This, besides its size, serves to distinguish it from the white pus or lymph-corpuscle. The professor adds to his account of the action of this powerful poison that he has many reasons for believing that the *materies morbi* of cholera is a nearly allied animal poison.

Nitrite of Amyl in Angina Pectoris.—Dr. T. Lander Brunton (*Lancet*) gives some very interesting results of the treatment of that distressing complaint, angina pectoris, by this new compound. He was first impressed with its value as a therapeutic agent after witnessing some experiments with it by Dr. Arthur Gamgee, of Edinburgh. The effect of its administration seemed to be the lessening of the arterial tension and the induction of capillary congestion; this, together with the assertion of Dr. B. W. Richardson, that while under its influence there was a paralysis of the nerves from the periphery inwards, as well as the fact propounded by Guthrie (Jour. of Chem. Soc., 1859) that it was of utility as a resuscitative agent in drowning, suffocation, and prolonged fainting, led him to use it in a case of obstinate anginal pain, which lasted in paroxysms for an hour to an hour and a half, and recurred every night.

In reference to its action in this and other cases he says:—

"On pouring from five to ten drops of the nitrite on a cloth and giving it to the patient to inhale, the physiological action took place in from thirty to sixty seconds; and simultaneously with the flushing of the face the pain completely disappeared, and generally did not return till its wonted time next night. Occasionally it began to return about five minutes after its first disappearance; but on giving a few drops more it again disappeared, and did not return. On a few occasions I have found that while the pain disappeared from every

other part of the chest, it remained persistent at a spot about two inches to the inside of the right nipple, and the action of the remedy had to be kept up for several minutes before this completely subsided. In almost all the other cases in which I have given it, as well as in those in which it has been tried by my friends, the pain has at once completely disappeared. In cases of aneurism, where the pain was constant, inhalation of the nitrite gave no relief, but where it was spasmodic or subject to occasional exacerbations it either completely removed or greatly relieved it. It may be as well to note that in those cases in which it failed, small bleedings were likewise useless.

"From observations during the attack, and from an examination of numerous sphygmographic tracings taken while the patients were free from pain, while it was coming on, at its height, passing off under the influence of amyl, and again completely gone, I find that when the attack comes on gradually the pulse becomes smaller, and the arterial tension greater as the pain increases in severity. During the attack the breathing is quick, the pulse small and rapid, and the arterial tension high, owing, I believe, to contraction of the systemic capillaries. As the nitrite is inhaled the pulse becomes slower and fuller, the tension diminished, and the breathing less hurried. On those occasions when the pain returned after an interval of a few minutes, the pulse, though showing little tension, remained small in volume, and not till the volume as well as tension of the pulse became normal, did I feel sure that the pain would not return.

"As patients who suffer from angina are apt to become plethoric, and greater relaxation of the vessels is then required before the tension is sufficiently lowered, I think it is advisable to take away a few ounces of blood every few weeks. When the remedy is used for a long time, the dose requires to be increased before the effect is produced. A less quantity is sufficient when it is used with a cone of blotting-paper, as recommended by Dr. Richardson, than when it is poured on a large cloth. From its power of paralysing both nerves and muscles, Dr. Richardson thinks it may prove useful in tetanus; and I believe that, by relaxing the spasm of the bronchial tubes, it might be very beneficial in spasmodic asthma. I have tried it in a case of epilepsy, but the duration of the fit seemed little affected by it. It produces relief in some kinds of headache, and in one of neuralgia of the scalp it relieved the severe shooting pain, though an aching feeling still remained."

Singular Case of Abscess in the Situation of Femoral Hernia, Containing Air. By F. D. Lente, M.D., of Cold Spring, N. Y.—Miss G—, aged 54, usually enjoying good health, was attacked suddenly, March 22, 1867, while coughing moderately, with severe pain or "cramp" in the hypogastrium, which continued to occur in paroxysms, notwithstanding hot fomentations, etc. Patient had had similar attacks, at long intervals, for several years, always produced by coughing, and she could arrest the action of the diaphragm to avoid acting painfully on the abdominal viscera. The pain seemed to her to be connected with the bladder, and to induce a disposition to pass water frequently. There was also some bearing-down pain, and anodynes were prescribed *per rectum*. The anodynes occasioned some nausea, which had not existed before, and the bowels had been regular. The next day the pulse was 100. She had less strangury pain, but complained of pain across the abdomen, at the level of the umbilicus, and extending to the spine, of a boring character; also of a pain along the lower part of the back, especially in attempting to assume a sitting posture. No distension of abdomen, and no pain on pressure. On thorough examination, a tumor was observed in the right groin, below Poupart's ligament. Patient says it appeared suddenly some years ago, and has never given "the least uneasiness;" is oval in shape, its long diameter parallel with Poupart's ligament, somewhat larger than a pigeon's egg, movable, and not painful on firm pressure. There was no appearance of the neck of a hernia above the ligament, and no pain on pressure in that locality. Simple enemas were ordered, and anodynes. March 31st.—The enema acted well. The tumor was sore after the manipulation, but patient up and about the room. In the evening had a recurrence of pain. April 3d.—Pain still confined to the region of umbilicus mainly, extending to the spine, aggravated by sitting up. Has also some bearing down and tenesmus. Bowels move regularly and without pain, and no nausea. Tumor much inflamed, and the induration extending to surrounding areolar tissue, but not *above* Poupart's ligament. No pain on pressure over any part of the abdomen. Pulse good; ordered cataplasms and anodynes. April 10th.—Still obliged to use anodyne enemata. No nausea, and bowels move daily. Inflammation of tumor increased, and extends several inches around the femoral ring. For some days it has been softening, and fluctuation distinct. Has a peculiar feel, different from an ordinary abscess in a "ripe" condition. Determined to lay open the abscess, and having an idea of possible connection with hernia, first punctured with an exploring knife, the withdrawal of which was followed by a slight puff of gas of an odor unmistakably *fœcal*. A probe being introduced, another puff followed. On entering the abscess with the scalpel, a gush of fetid gas was followed by several ounces of dark, unhealthy pus, but no feculent matter. The finger, introduced into the cavity, could be passed in various directions, but did not enter the abdominal cavity. May 23d.—Great relief followed the evacuation of the contents of the abscess, though the pains continued for several days; is now quite well, and moves about the house. The wound is not quite healed. Was this a suppurating gland or a hernia? If the latter, it might possibly be an instance of protrusion through the thyroid foramen, and if a hernia, it must have been of the cæcum, since there was never any constipation. If it was a hernia, would there not have been disturbance of the functions of the abdomen, and other symptoms than the boring pain across the abdomen? There was no appearance of gangrene about the abscess.—*N. Y. Medical Journal.*

A Convenient Hæmostatic. By A. P. Merrill M.D.—A combination of elixir of vitriol and tannic acid has been recommended for this purpose, but I was not aware of its value until, in 1857, I accompanied a patient to the office of the late Dr. Horace Green, to obtain the benefit of his skill as a specialist in diseases of the throat. The tonsils, although not enlarged, the doctor thought in a morbid condition, and he pared a thin slice from the surface of each. Only a little bleeding followed during the day, but at two o'clock that night his wife discovered that his pillow was bloody, and called me from my bed in the same hotel. I found his pulse feeble, breathing labored, and strength greatly prostrated; and he soon vomited a large quantity of blood which had been swallowed. I could see the pulsations of a bleeding artery in one of the tonsils, and there was an oozing of blood from the cut surfaces. Having no other remedy at hand, I made a mixture of elixir of vitriol and tannic acid, and applying freely, the hæmorrhage was immediately and permanently arrested.

Since that time I have used this mixture in various internal and external hæmorrhages, and with uniform success. I am now inclined to the opinion, that whatever can be effected in such cases, and even in diarrhœa, by astringents, may be done by this remedy; and in emergencies it is more likely to be found within convenient reach than most other remedies of this class. A touch of the tongue with this combination, made in the strength of a saturated solution, will convince any one of its powerful astringency.

KOBERLE ON THE AMPUTATION OF THE UTERUS.—The *Gaz. des Hôpitaux*, No. 70, 1866, reports according to the *American Medical Times*, January, 1866 (?) and *Gaz. Hebdom.*, No. 11, 1866, that operative surgery now undertakes procedures which were formerly held to be impracticable. This is true of ovariotomy and the extirpation of the uterus by the abdominal walls. The latter operation is said to have been first performed by Clay, an American, in 1847, and that then it was performed by several foreign surgeons, and in France by Koberle. The last operation was by Storer, of Boston, in September, 1865. (Dr. Storer's case is familiar to our readers; he having removed the entire uterus, on account of an enormous fibrous tumor weighing thirty-seven pounds.) Up to this time there have been twenty-four extirpations of the uterus and both ovaries; of the former seventeen two recovered; of the latter seven four recovered.

Koberle remarked that the above account was incorrect. The first extirpation of the uterus was performed by Heath in Manchester, England, and the first one with a successful result by Burnham of Lowell, Massachusetts, in 1853. The known number of operations, with or without removal of both ovaries, is forty-two, with eight cures and thirty-four deaths, that is, one cure in every five cases.

The extirpation of the uterus is a much more grave and difficult operation than that of the ovaries. The most of the operations have been performed on account of errors in diagnosis. More than a third of the cases bled to exhaustion during the operation or soon after. Burnham had performed the operation most frequently; nine times, and twice with success. Koberle had had two favorable results in five cases. The deaths were from hæmorrhage. In the first case a vein which was not ligated caused a fatal oozing, much blood having already been lost during the operation. In the second case a ligature slipped off during the operation, and a fearful hæmorrhage quickly destroyed life. In the third case the operation was very difficult, on account of adhesions over the entire surface, and complication with ascites. In this case Nelaton had previously diagnosticated an ovarian cyst, and had made injections of iodine to the right and left of the tumor, in the abdominal cavity (Bauchbohle), and had thus caused the general adhesions. The ovaries were found healthy and not removed.

The operation lasted nearly three hours, and was accompanied by severe hæmorrhage. The first successful result occurred in 1863. The two ovaries, the uterus, and a fibroid weighing seven kilogrammes (more than fifteen pounds) were removed. This patient is still alive and well. The second was reported in the *Gaz. Med., Strassbourg*, 1866, No. 5, at the same time with a favorable result in a case of polypus with an irreducible inversion of the uterus. The operation took place March 6, 1866. The inversion was twenty-six centimetres long (about eight and two-third inches). The puncture of the tumor, which was considered an ovarian growth, had no result. Then Koberle recognized it as the fibrous tumor, which was developed from the right superior wall of the uterus. The broad uterine ligament on the right side was twice ligated and then divided between the ligatures. An iron wire loop was then firmly secured around the upper part (in der Hohe) of the neck of the womb, the left ovary and tube (Fallopian) seized with it, and the tumor cut off some centimetres above the wire. It weighed five kilogrammes (more than ten pounds). The ovaries were healthy. The wound united without any peculiar applications, the lower angle being left open. The ligature of the uterus fell off with the dead stump in ten days.

The patient recovered without any accident, except that some months after an abscess opened in the rectum. Since then she has been perfectly well.

Besides the abdominal incision for the purpose of extirpation of the uterus in fibroid tumors, gastrotomy has been performed twenty times, in order to ligate or enucleate pediculated fibroid tumors, and eight times with success. In fourteen other cases the operation was not completed, and of these, there were five fatal results.—*E. Koberle, Documents pour servir à l'histoire de l'extirpation des tumeurs fibreuses de la matrice par la méthode sus pertrenne. Paris*, 1865. *Monatsschrift fur Geburtskunde, Band* 27, 5 *Heft, from Gaz. des Hôpitaux, No.* 72, 1866.

ON THE SUBCUTANEOUS INJECTION OF QUININE IN CASES OF MALARIAL NEURALGIA, by E. C. SEGUIN, M.D., Resident Physician New York Hospital.—Several cases are related from the hospital case-book, illustrating "the effect of quinine injected hypodermically over the seat of neuralgias due to blood-poisoning by malaria." All such cases had previously been treated by quinine and iron internally, with blisters over the affected part. This treatment was not satisfactory; the usual term of hospital residence being from three weeks to three months. Dr. W. H. Draper directed, in the first case related, the injection of quinine. "In four days the pain was relieved, and in four more the cure was complete and permanent; the case having previously been under treatment five weeks without benefit." The following is the formula used: Quin. sulph., grs. lx.; acid. sulph.dil. gtt. xl.; aquæ dist. ℥ j.; mix, and make a solution, filtering with care. xxxv. minims are equal to four grains of quinine. "The injections were given in the following manner: A fold of skin being taken up, and firmly held between the thumb and finger, the point of the syringe was introduced at the top of the fold, where a partial anæsthesia had been produced by the pressure; the needle being put in its full length, the solution was forced in gradually, as the needle was withdrawn, so as to throw the liquid as much as possible into the track of the wound, and to cause the least rupture of the surrounding connective tissue. After removing the syringe, a little circular friction was used to assist absorption. The immediate effect of the injection is a pretty severe burning pain felt in the part, due, probably, to the acid and irritating property of the solution. The therapeutic effect of the medication shows itself in the arrest of the pain and hyperæsthesia, followed, in some instances, by slight, though distinct local anæsthesia. No abscesses or other unpleasant symptoms have followed the seventy-eight injections used in the cases mentioned." The *modus operandi* may be said to be three-fold. 1st. By absorption of the drug, whereby it obtains its specific effect tending to the removal of the cause of the neuralgia. 2d. By direct therapeutic action of the quinia upon the nerves and cellular elements of the parts affected. 3d. By pressure; a purely mechanical effect of considerable importance, due to the large quantity of fluid used, and to the amount of exudation thrown out. Of the six cases related, the subjects were all seamen from Southern

ports, and all had the malarial cachexia, having had remittent or intermittent fever before the coming on of the pain. In none of the cases was the pain intermittent, nor was it of the same intensity during the twenty-four hours, being usually more distinct in the afternoon. The internal administration of iron and cinchona was used in connection with and for some time after the injections were discontinued.

Raw Flesh and Brandy in the Treatment of Phthisis.—1. The exhibition of raw beef and mutton, and of alcohol, in doses varying according to circumstances, arrests the progress of pulmonary phthisis and other consumptive diseases. Under the influence of this mode of treatment, strength is restored, the countenance recovers its animation, appetite returns, and the patient gains in flesh and weight. In a month, or even in three weeks, in several cases, the body gained four, six, eight, and even as much as twelve pounds. 2. This general improvement of the system, aided by appropriate treatment of the leading symptoms, checks the hectic fever, diarrhœa, and night-sweats. 3. When these complications have yielded, amendment of the local condition of the lungs, or other diseased organs, sets in, and the advance of cicatrization can be ascertained by percussion and auscultation. 4. The efficacy of the treatment is not equal in all stages of the disease. In the third stage, the improvement in general is confined to a prolongation of life, the inevitable issue being merely postponed. In the second stage only can the treatment be said to be curative, provided all the necessary precautions are strictly attended to. Of all atrophic diseases in which the treatment is applicable, that in which the greatest measure of benefit is obtainable is pulmonary tuberculosis, in all its stages. It is also highly beneficial in every form of anæmia, whether resulting from hæmorrhage or spermatorrhœa; at the conclusion of acute affections, especially typhus and typhoid fevers, in the last stage of leucæmia, albuminuria, and diabetes; it is also frequently successful in pyæmia, paludal cachexia, chronic nervous fever, and in general in all protracted morbid conditions in which repair is obviously unequal to the expenditure of the system.—*Jour. of Pract. Med. & Surg.*

Poisoning by Strychnine; Recovery after taking Three Grains.—Mr. W. H. Folker reports in a recent number of the *Lancet*, a case of the above. The patient took three grains of the alkaloid for suicidal purposes. The first spasm came on in three-quarters of an hour. The severest paroxysm occurred in an hour and fifty minutes. The spasms ceased in twelve hours. The face was calm, and free from the risus sardonicus of ordinary tetanus. The intellect was clear throughout, although screaming was present, together with a dread of being touched—similar to that witnessed in hydrophobia. Touching, and the effort of swallowing, directly produced a spasm. The spasms were very irregular in their occurrence. Chloroform was apparently the remedy which brought about the good result. In this respect the case bears a striking analogy to the one reported in our columns (March 1, 1867) by Dr. Hamilton, of Chardon.

Blotting Paper as a Dressing.—Dr. Roser (*Schmidt's Jahrbücher*) recommends blotting-paper as a very cheap and serviceable surgical dressing. It is to be applied either in broad pieces or in separate layers so placed in reference to each other that the edge of each leaf is directed toward the pus to be absorbed.

Starch Injections in Urethritis.—M. Luc (*Recueil des Mémoires de Med. et de Chirurg. Militaires*) uses with great success a tolerably thick solution of starch in cases of acute urethritis. He says: "It never produces pain, and avoids strictures."

Examination of the External Auditory Passage.—In the interesting article from my friend Dr. Shaw, on this subject, in your journal for May 30th, occurs the following sentence: "From the great uncertainty which attends the weather, recourse must be had to artificial light, which will be found an efficient substitute" (that is for ordinary daylight or sunlight). One of the great advantages which the method of illumination of Von Tröltsch, of which Dr. Shaw justly speaks so highly, is, as it seems to me, the fact that we are *never obliged* to substitute lamp or gaslight for ordinary daylight, even if the weather be cloudy or stormy. I have never as yet seen the daylight which was not sufficient to fully illuminate the auditory canal and membrana tympani, when reflected by the concave mirror. Believing, as I do, that the introduction of this simple means of examination has done more for the advance of our knowledge in ear disease than any one suggestion ever made in this province, I am induced to ask you to insert this as an addendum to an article which has done a real service to the profession. If I am correct in my views of the adaptability of the mirror to any weather, cloudy or pleasant, its use becomes still more simple.—*D. B. St. John Roosa, Bost. Med. & Surg. Jour.*

Case of Papillary Growth in the Armpit; Cure by the Electrolytic Method.—A lady presented herself, Nov. 21, 1866, on account of a small papillary and highly vascular growth, which had first appeared in the right axilla, since the commencement of 1865, and had somewhat rapidly increased in size during the last few months. It was one-third of an inch long, and one-fourth of an inch wide in its widest part. I introduced a needle connected with fifteen cells of the battery into the base of the tumor, and allowed the current to pass for three minutes. No chloroform or ether spray was used. The current had not acted many seconds, when a peculiar change was observed in the tumor, which lost its flesh color, and appeared quite white, as if it had been frozen. When the needle was withdrawn, circulation in the tumor had evidently quite ceased. There was scarcely any pain during the operation, and none at all afterwards, nor was any blood lost. Nov. 23.—Tumor entirely shrivelled up, looking like a thin brown leaf just adhering to the skin. The operation, therefore, was not repeated. Dec.—The eschar fell off about a week after the operation. There is now no sign that there ever was a tumor, no scar, nor even redness of the skin perceptible.—*Dr. Julius Althaus in the Brit. Med. Journ.*

Death from Chloroform on its Third Administration.—Assistant-Surgeon H. A. Du Bois, U.S.A., in the *N. Y. Med. Journal*, communicates a report of a case of death by chloroform in a patient about thirty-five years old, suffering from scrofulous disease of the testicle. The testicle on the first examination was found considerably enlarged; an incision gave exit to a quantity of pus, and after treatment for some time, a fungous growth was removed, together with a greater part of the testicle, by Syme's operation. The wound soon healed, and the patient was discharged cured. It required two ounces of chloroform to bring him under its full influence. He struggled violently, and had a number of tonic spasms. In three months he again presented himself, the other testicle having taken on the disease, and after treatment for some time, it was removed. About a half ounce of chloroform was used on this occasion, the patient coming under its influence with little difficulty. The wound

healed to a great extent, though at the end of two or three weeks one of the ligatures still remained firmly held. So much pain was induced by the attempt to remove it, that chloroform was again resorted to. About a drachm was put on a small towel, loosely folded in the form of a cone, and with the apex well opened, I proceeded to put him under its influence. He stated that he was coming under its influence easily, and that he hoped he would not cause as much trouble as before. He breathed well, and appeared to be rapidly becoming affected. The second stage coming on, he threw his arms about, so that it required an assistant to hold him, though not to the extent that one frequently sees; the breathing suddenly becoming stertorous, the chloroform, which had been renewed to the extent of one fluid-drachm, was discontinued. The patient lay on the bed, and I watched attentively the moment when the eyelids would show, by their relaxed condition, that the patient was sufficiently under the influence of the anæsthetic to perform the trifling operation required. The stertor was followed by a spasm, causing the body to assume the condition of opisthotonos, and to slide down in the bed, the face assuming a peculiar expression, which alarmed and caused me to throw water on the face and abdomen. The limbs now became relaxed, the spasm having ceased, and having lasted about half a minute. The breathing was gasping, and he inspired at long intervals. I seized the tongue, and drew it out of the mouth, and commenced artificial respiration; sent for ammonia, hot water, and a magneto-electric machine, while I examined the heart, which was beating but feebly. Ammonia was applied to the nostrils, cold water to the chest and face, and hot to the abdomen. In the hope of restoring the breathing, artificial respiration was kept up, and a strong current of electricity was passed through the heart, through the throat, and through the length of the spinal cord. After a few gasping respirations, death took place. The means of resuscitation were kept up for some time after life had ceased, but without any effect. Death took place in from five to seven minutes after the commencement of the administration of the chloroform. The chloroform used was that prepared by Squibb. The quality of the chloroform was tested, but no impurity was detected. An autopsy, four hours after death, revealed a slight accumulation of fat over the pericardium and on the surface of the heart, an effusion of serum in the pericardium, heart structure firm, a few hardened tubercles at the apices of the lungs. At the apex of the left a well-marked cicatrix, the kidneys congested, measuring seven inches in length by four in width, spleen greatly enlarged, and the liver of normal consistence, and slightly increased in size. The spermatic cord was diseased for about two inches, and the ligature was nearly ulcerated through. Considerable fluid was effused between the dura and pia mater, and arachnoid. The cause of death could probably be explained by the condition of the kidneys. Patient had lost flesh from the commencement of the disease, had frequently complained of pain in the region of the kidneys, and at the time of the second admission was suffering from break-bone fever. Perhaps the chloroform acting upon the blood, already overcharged with excrementitious matter, may have produced the convulsion and caused the effusion, which may have been the cause of the cessation of the heart's action; though it is possible that the overloaded blood, when charged with chloroform, acted so as to cause paralysis of the heart.

THE UMBILICAL SOUFFLE; Dr. A. Charrier, Paris (*Gazette des Hôpitaux*).—The phenomenon named umbilical souffle, though rare, occurs more frequently than is generally supposed. It is in practice a premonitory symptom of very great importance. It indicates compression of the umbilical cord, and consequently, an impeded utero-fœtal circulation. The umbilical souffle may be intermittent or persistent. Intermittence diminishes the seriousness of the prognosis. Permanence of the souffle increases the gravity of the prognosis, particularly if alternate, and acceleration of the cardiac beats comes on, and afterwards violent movements of the fœtus, followed by a diminution both in the rhythm and in the number of the fœtal pulsations. When such symptoms occur, it is evident that the death of the fœtus is imminent. When the souffle is intermittent, it is the duty of the practitioner to abstain from action and wait; but he should watch attentively, by auscultation, the utero-fœtal circulation. If the souffle be persistent, and the phenomena of slow action, and acceleration of the cardiac pulsations of the fœtus, etc., are presented, the practitioner should step in and induce premature labor. The umbilical souffle is frequently produced by an accidental shortening of the cord. The accidental shortening of the funis is in direct relation to its length; for the longer the umbilical cord, the greater is its chance of becoming twisted round one or more parts of the fœtus, and so giving rise to disorders just mentioned. Accidental or natural shortening of the cord may be dangerous in the last stage of labor by this sign: an inversion of the fundus of the womb at the time of each pain, which inversion is reduced spontaneously after the cessation of the uterine contraction. The anatomical proof of this complete inversion of the uterus may be found in the premature separation of the placenta at its central part, in the presence of recent clots behind this organ, and in the rapid expulsion of the after-birth into the vagina almost immediately after the passage of the child.—*Half-Yearly Abstract.*

MILK AS A CARDIAC SEDATIVE.—Dr. Pecholier avers that under the influence of a milk diet, which he enjoins in the obstructive diseases of the heart, the impulse of the heart diminishes, together with the palpitation, and the congested condition of the face, the brain, and the lungs. The patient experiences unexpected improvement, and he thinks that by the adoption of this plan life may be prolonged.

FORECASTS OF WEATHER.—There are strong grounds for believing that the barometer may yet be made available in giving premonitions of storms. G. W. Hough, Director of the Dudley Observatory at Albany, stated, at the last meeting of the American Association for the Advancement of Science, that the observations made during the past year with his self-recording barometer confirmed the opinion advanced by him at a previous meeting that the barometric column is restless during a storm which may not be within several hundred miles of the instrument. The number of minute oscillations of the column, taken in connection with the movement apparent to the eye, will indicate the comparative severity of the storm. It is probable that one hundred similar instruments, properly distributed across our continent, would record the atmospheric changes with such minuteness that new and important generalizations might be arrived at.

A SIMPLE METHOD OF PROTECTING WATER FROM THE ACTION OF LEAD PIPE.—*Dingler's Polytechnisches Journal* publishes a simple method, brought forward by Dr. Schwarz, of Breslau, for preventing the poisonous influence of lead pipes on water, by forming, on the inside surface of the pipes, an insoluble sulphuret of lead, which has proved so effective that, after simple distilla-

tion, no trace of lead can be detected in water which has remained in the pipes for a long time. The operation, which is a very simple one, consists in filling the pipes with a warm and concentrated solution of sulphuret of potassium or sodium; the solution is left in contact with the lead for about fifteen minutes. Commonly, a solution of sulphur in caustic soda will answer the purpose, and produce, practically, the same results. It is known that sulphuret of lead is the most insoluble of all compounds of lead, and nature itself presents an example which justifies the theory of Dr. Schwarz, since water extracted from the mine of Galena does not contain lead, a fact which has often occasioned surprise. —*Journal of Applied Chemistry.*

New Method of Treating Abscess.—Mr. Joseph Lister, F.R.S., Prof. of Surgery in University of Glasgow, has sent a communication to the *Lancet* in which he describes a new method for treating abscess, by which he claims more than ordinary good results. His process is based upon the exclusion of those atmospheric germs which are supposed to keep up by their decomposition the pyogenic acid. The mode in which this is accomplished is as follows:

A solution of one part of crystallized carbolic acid in four parts of boiled linseed oil having been prepared, a piece of rag from four to six inches square is dipped in the oily mixture, and laid upon the skin where the incision is to be made. The lower edge of the rag being then raised, while the upper edge is kept from slipping by an assistant, a common scalpel or bistoury dipped in the oil is plunged into the cavity of the abscess, and an opening about three-quarters of an inch in length is made, and the instant the knife is withdrawn the rag is dropped upon the skin as an antiseptic curtain, beneath which the pus flows out into a vessel placed to receive it. The cavity of the abscess is firmly pressed, so as to force out all existing pus as nearly as may be (the old fear of doing mischief by rough treatment of the pyogenic membrane being quite ill-founded); and if there be much oozing of blood, or if there be a considerable thickness of parts between the abscess and the surface, a piece of lint dipped in the antiseptic oil is introduced into the incision to check bleeding and prevent primary adhesion, which is otherwise very apt to occur. The introduction of the lint is effected as rapidly as may be, and under the protection of the antiseptic rag. Thus the evacuation of the original contents is accomplished with perfect security against the introduction of living germs. This, however, would be of no avail unless an antiseptic dressing could be applied that would effectually prevent the decomposition of the stream of pus constantly flowing out beneath it. After numerous disappointments, I have succeeded with the following, which may be relied upon as absolutely trustworthy. About six teaspoonfuls of the above-mentioned solution of carbolic acid in linseed oil are mixed up with common whiting (carbonate of lime) to the consistence of a firm paste, which is in fact glazier's putty with the addition of a little carbolic acid. This is spread upon a piece of sheet block tin about six inches square; or common tinfoil will answer equally well if strengthened with adhesive plaster to prevent it from tearing, and in some situations it is preferable, from its adapting itself more readily to the shape of the part affected. The putty forms a layer about a quarter of an inch thick; it may be spread with a table-knife, or pressed out with the hand, a towel being temporarily interposed to prevent the putty from sticking to the hand or soiling the coat-sleeve. The tin thus spread with putty is placed upon the skin so that the middle of it corresponds to the position of the incision, the antiseptic rag used in opening the abscess being removed the instant before. The tin is then fixed securely by adhesive plaster, the lowest edge being left free for the escape of the discharge into a folded towel placed over it and secured by a bandage. This dressing has the following advantages: The tin prevents the evaporation of the carbolic acid, which escapes readily through any organic tissue such as oiled silk or gutta-percha. The putty contains the carbolic acid just sufficiently diluted to prevent its excoriating the skin, while its substance serves as a reservoir of the acid during the intervals between the dressings. Its oily nature and tenacity prevent it from being washed away by the discharge, which all oozes out beneath it as fast as it escapes from the incision; while the extent of the surface of the putty renders it securely antiseptic. Lastly, the putty is a cleanly application, and gives the surgeon very little trouble; a supply being daily made by some convalescent in a hospital, or in private practice by the nurse or a friend of the patient; or a larger quantity may be made at once, and kept in a tin canister. The dressing is changed, as a general rule, once in twenty-four hours; but if the abscess be a very large one, it is prudent to see the patient twelve hours after it has been opened, when, if the towel should be much stained with discharge, the dressing should be changed, to avoid subjecting its antiseptic virtues to too severe a test. But after the first twenty-four hours, a single daily dressing is sufficient. The changing of the dressing must be methodically done, as follows: A second similar piece of tin having been spread with the putty, a piece of rag is dipped in the oily solution, and placed on the incision the moment the first tin is removed. This guards against the possibility of mischief occurring during the cleansing of the skin with a dry cloth and pressing out any discharge which may exist in the cavity. If a plug of lint was introduced when the abscess was opened, it is removed under cover of the antiseptic rag, which is taken off at the moment when the new tin is to be applied. The same process is continued daily till the sinus closes.

Longevity in England.—Among the deaths registered in England in the year 1865, there were twenty-one men and sixty-eight women above a hundred years old, viz.: five men and twenty-five women, aged one hundred; four men and fifteen women, aged one hundred and one; five men and eleven women, aged one hundred and two; three men and four women, aged one hundred and three; one man and seven women, aged one hundred and four; two men and four women, aged one hundred and five; one woman, aged one hundred and six; one man and one woman, aged one hundred and ten.

Population of the Earth.—In the first volume of Dr. Behm's "Geographical Annual," lately published at Gotha, there is an interesting article on the population of the earth. This was estimated by Busching in 1787 at 1,000,000,000, by Fabri and Stein in 1800 at 900,000,000, by Horschelmann in 1833 at 872,000,000, by Dieterici in 1858 at 1,288,000,000, and by Kolb in 1865 at 1,220,000,000. Dr. Behm estimates it at 1,350,000,000, thus distributed: Europe, 285,000,000; Asia, 796,600,000; Australia and Polynesia, 3,850,000; Africa, 188,000; and America, 74,500,000. At the same time he acknowledges that it is impossible to arrive at anything more than an approximate notion of the population in Asia and Africa, there being no census or other accurate means of ascertaining the number of inhabitants in those continents.

MEDICAL PROPHETS.

THERE is nothing so encouraging to the physician as the absolute confidence of his patient. The thought that his actions are approved by the one who has entrusted life to his hands serves to assuage, in a degree which nothing else can, the many anxieties and perplexities to which every practitioner is more or less a prey. There is in such an understanding a mutual sharing of a responsibility, which is encouraging to both parties, and enables each to perform to infinite good advantage his duty to the other.

This blind belief in the skill and understanding of the physician is not so strong as it has been; but this is not so much due to the patient as to the physician. The former does not of choice barter the comforts of such a faith in the wonderful properties of drugs, and in the immaculate opinions of the doctor, for the present fashionable and hollow gratification of sneering at medicine as an uncertain science. To very many the mere summoning of a physician means recovery; and his presence in the sick-chamber has not inaptly been likened in effect to that of a ministering angel.

But these, alas! are getting to be in the minority. We have no hesitation in saying that one of the main reasons for this has reference to the propensity among us of making ourselves almost prophets. We are not content to trust to nature and our remedies, but are constantly accustoming ourselves to indulge in unreasonable and thoughtless conjectures as to the issue of the disease, and most generally, in nine cases out of ten, stultifying ourselves in the eyes of our patients by a false prognosis. Nothing, in our opinion, tends more certainly to destroy the confidence of a patient in his medical adviser, than to have it become apparent that such a mistake has been made. Among physicians the reasons are in the main obvious enough; but to outsiders, who have not sufficient knowledge of the laws of disease, and their disposition to an ofttimes treacherous modification, there is no excuse, save that which refers to culpable ignorance. How often we have had occasion to hear that such and such an individual, apparently in perfect health, had been condemned to speedy death years before by his physician; and how often we have thought that the disagreeable reflection which is thereby cast upon the skill of our brother might have been prevented by more caution on his part. There is hardly a community that can be found in which some such story of this kind concerning a practitioner is not afloat. The error lies more in condemning our patients too soon to death than in promising them a cure. We are not, in truth, sufficiently well acquainted with the curative power of Nature to enable us fairly to appreciate it. An old practitioner once gave us the advice never to deliver a child to death until the breath had actually left the body, for truly did he say that care and patience might fan the slightest spark of animation into a blaze of reaction. Every practitioner in midwifery can attest the truth of this from the moment the child becomes an independent being; and it is only because many of us forget that the vital principle in a child of two years of age is as strong as it was at birth that we are so ready to give unfavorable prognoses in such cases.

Virtually, the same facts may apply to the constitutional stamina of different cases; for in very many we find most astonishing recoveries taking place in the very face of death itself, and in contradiction to all the legitimate relations between cause and effect. How often have such cases actually rallied under the very hand of the one who had already cut the sufferer loose from every human hope! If, in such an instance, the physician has given a cautious prognosis, he gains the credit of a remarkable cure; but if otherwise, he is not only cheated of his just meed of praise for the proper management of the case, but is called an ignoramus besides.

Another foolish practice is that of predicting the time of death. It is a temptation into which many have fallen, and the majority have had reason to be chagrined at many an inexplicable mistake.

We recollect a case in point, in which a female was shot, and the ball having entered a vital part, the patient was allowed only an hour to live. The public took a great interest in the unfortunate victim; and, to satisfy the cravings for news, bulletins appeared daily for a month or more, predicting an almost hourly death, until many of the secular papers were forced to comment upon the value of an opinion so obviously faulty. Finally, a long time after, the patient did actually die, but evidently not for the reason that the doctor said she must.

If we perchance make a wrong diagnosis, the mistake is by no means so apparent to our patient; but let us by any miscalculation surrender to death a sufferer who is determined to live despite our decision, and we give to the laymen an incontestable and glaring proof of our ignorance—a something which to them cannot be explained away by any of the subtleties of medical logic.

The constant occurrence of these mistakes should

teach us the all-important lesson, to be on our guard in giving any prognosis, but leave, as we have a right to do, a loophole through which we can save the integrity of our opinion. When we consider how impossible it is to foretell death in the vast majority of instances, it is surprising to find how physicians will hazard their reputations as skilful observers, by predicting the result in such positive terms.

It is natural for the patient's friends to be anxious in regard to the result of the case of the sick one, but they cannot, in reason, ask for anything more than an opinion. The physician can give this in a sufficiently qualified way, not only to satisfy his questioner, but protect himself in case the result be such as had not been anticipated. But the trouble with most of us who have not been unfortunate enough to make any mistake in prognosis is, in the ecstasy of a presumably correct diagnosis, to rush, by way of bolstering it up, at once into a prognosis which is too apt to be unqualifiedly *pro* or *con*.

Every one who has been long in practice has proved to himself the great uncertainty of death as well as of life, and has learned to make his calculations accordingly. The very useful lesson to be learned is that of never surrendering the patient to death with folded hands, but standing by his bedside as a faithful minister to the last, hoping that, if a cure cannot be effected, the malady may be at least mitigated in the severity of its symptoms, and the coming of death retarded. In the present state of our science it is, to say the least, hazardous for any medical man to give up his case as absolutely hopeless, and allow any assertion to overreach the bounds of probability. Aside from the capriciousness of nature, and the modifying effects of different constitutions, idiosyncrasies, and other no less important conditions, the chances are that a mistake in diagnosis may be made which, as the foundation of all prognoses, would render the latter valueless. Another reason is, we do not study the approach of death enough.

The haste to give up a case in despair explains in one way the success of the charlatans, who are ever ready to seize upon the so-called desperate ones and make capital of them. If, under such circumstances, a mistake is made, as is too apt to be the case, and the patient gets well, it is of course due to the remarkably curative powers of the quack's nostrum.

As probably nearly every member of our profession has read the Code of Medical Ethics adopted by the American Medical Association, and having read, could not well avoid being impressed with the lightness of its burdens, we presume it will be unnecessary to state that its edict is a sermon against the recognition of quackery in any and every form. There is no attempt whatever to conceal its animosity toward all unmanly subterfuges, and none to entrap the unwary—its language is told simple, unmistakable—it confers certain immunities, and demands certain conditions in return. No man is dragooned into obedience to its laws—the act must be voluntary, and the step taken with circumspection. We are led to make these remarks in view of a recent episode in the proceedings of the N. Y. Academy of Medicine, which the public press is determined shall pass into history.

The facts are these: One of its fellows was arraigned for violating the code, in that he had held repeated consultations with "a homœopathic physician, so called." The charge was admitted, but sought to be extenuated on the ground of ignorance regarding the professional heresies of one of the parties in question. The plea failed, and the Academy adopted the recommendation of its committee on ethics, that the delinquent be suspended from membership for an indefinite period; at the same time intimating that after due penitence and recantation, he would be restored to former privileges. The case being lost, and the verdict esteemed "a blessing in disguise," the determination "to die game" was neither surprising nor unnatural. The kind intentions of the committee being thus thwarted, assumed the character of a misapprehended mercy, and the victim, by the aid of the secular press, has since been advertised into the seventh heaven of martyrdom.

"He has been kicked out of the Academy," says the *Tribune*. "His parchment is of no more use to him now than if he had cut it out of a drum-head. Whatever may have been his services to the sick and suffering during his twenty-three years' practice, whatever his accuracy in diagnosis, his skill in prescription, his faithfulness to duty, his success, his reputation, his general standing among physicians—there is no doubt about him now; he is a pariah and an outcast. He need not expect any more fees. He may take down his sign and sell his gig. Patients are warned to keep away from him, and, to use the language of one of the 'regular' gentlemen who have brought upon him this dreadful doom, he is probably at the present moment 'wandering alone' in this great city and dying 'a living death.'"

The spectacle is a moving one, and slightly melodramatic, but there is a painful impression of blue fire, the first murderer, and the slow music.

Meanwhile, too, the Academy, after these terrible onslaughts, is beginning to recover its self-possession, and to become accustomed to its bereavement; the victim of persecution has had the advantage of first-class notices in the *Times* and *Tribune*, some bad rhetoric has been expended, and all the parties are to be supposed as being very well pleased with the denouement.

Our attention has been called to an oversight of our own in a recent report of the lecture by Dr. Warren Stone on yellow fever. By mistake of the reporter the lecture is represented as having been delivered in Bellevue Hospital instead of Bellevue Hospital Medical College. We make the correction with pleasure, particularly since we are also indebted to the pub-

lic spirit of this flourishing college for the very acceptable lecture of T. Spencer Wells.

The different medical colleges have regularly inaugurated their winter courses, and the attendance of students is generally as large as it has ever been heretofore, and there is, besides, a reasonable prospect of an increase. All our schools are well managed, and richly deserve encouraging patronage.

Reports of Societies.

N. Y. PATHOLOGICAL SOCIETY.

STATED MEETING, SEPTEMBER 11, 1867.

DR. WM. B. BIBBINS, CHAIRMAN *pro tem.*

CANCEROUS DISEASE OF THE SIGMOID FLEXURE.

DR. SAYRE exhibited a specimen of which he gave the following account:

On the 7th of July, I was called about one o'clock at night, by Dr. Davis of this city, to see a patient in 19th street, who was said to be suffering from obstinate constipation, with the request that I should bring some injecting instruments. The man was 46 years of age, remarkably stout and healthy-looking, and weighing about two hundred and fifty pounds. He stated that being an active business man, he had enjoyed remarkably good health, not having been laid up with sickness for twenty years past. I found his abdomen distended to its utmost capacity, and the patient making all the time ineffectual efforts at stool. This was Tuesday, and he had had no passage since the Saturday previous, when, as he stated, he had his usual difficulty at stool which he had suffered from for a year past, consisting in the necessity for an injection. During this latter period, however, he had never been so troubled as to seek for medical advice. The physician had been trying to get a passage through him for the past two days, but without success. By exploring his anus with the finger I could find no obstruction, but on passing up a flexible rectal bougie for eight or nine inches, I came across a positive stricture, which was so firm that I could not penetrate it at all. The abdomen was very much distended, and he being very fat withal, it was some time before I could satisfy myself of the existence of a tumor in the situation of the sigmoid flexure. Having settled upon this diagnosis, I stated that there was no hope for him, and that he most certainly must die very soon. He received the intelligence very composedly, and died at the end of twenty-four hours after.

On making a post-mortem examination, twenty-four hours after death, the colon was found immensely distended, in some places being as large round as a man's arm. There was no enteritis present, neither was there any general peritonitis to be met with. At the sigmoid flexure a hardened mass was discovered, which was impervious to water from above and below. On removing the mass subsequently, it was found to block up the gut so completely as to barely admit the passage of a fine probe. The tumor was scirrhous-cancer, and it was very remarkable that a disease so extensive as this has been, as is seen by the specimen, could have existed without pain, or any serious inconvenience, until within a few days of his death.

PUERPERAL CONVULSIONS OCCASIONED BY ALLOWING PLACENTA TO REMAIN TOO LONG IN UTERO—A HOMŒOPATHIC MISTAKE.

DR. SAYRE next presented a specimen which he said was interesting, not strictly in a pathological point of view, but in connection more particularly with the circumstances which brought it to light.

At the last meeting of the society, June 27, he was suddenly called away by a gentleman, who met him at the door, with the statement that his (the messenger's) daughter was dying, and that he should immediately repair to the house. On the way thither he stated that his daughter had been confined the evening before at five o'clock, and was attended by Dr. ——— of this city, a prominent homœopath, who, after having delivered her of a fine healthy boy, had left the house with an assurance to the patient and her friends that everything was all right. In the course of a few hours afterwards, the homœopath was summoned in great haste to find his patient in a convulsion. He then called in another distinguished homœopath in consultation. They together were with the patient most of the day, during which time she had frequent convulsions. Finally, at nine o'clock in the evening, they stated that it was impossible for her to survive, and a clergyman was accordingly sent for. As Dr. Sayre entered the house, the mother of the patient came down to state that the two homœopaths had just left, and that a marked change had come over her daughter, that the medicine was beginning to act, and that they thought that there was just one chance in a thousand for recovery, and begged that Dr. S. should not see her for fear that any change of treatment might be positively fatal. The father accordingly apologized, and Dr. S. was about leaving, when a servant came down to say that Mrs. A—— was in a fit. Dr. Sayre was then requested to see the patient, and found her in a severe convulsion; her tongue was protruded from her mouth, covered with bloody froth which issued also from the nostrils, while her face was black. Girdling her arms and legs with handkerchiefs, and by *sudden twitches* producing a shock on her nervous system, and by artificial respiration he succeeded in restoring the circulation, which had nearly ceased. He then proceeded to examine the uterus. He found the os largely dilated, and then felt what he supposed to be a clot of blood, but on passing his hand up into the cavity of the organ, he found that the mass was too large to be taken away without danger from hæmorrhage, and accordingly administered ergot to expedite matters. As the result, the mass was removed, which proved to be the *placenta* entire, with the exception of a small piece that had been torn off with the cord.

In conclusion, he stated that he thought that it was his duty to report the case as he had done, in order to expose to the community a fair sample of homœopathic practice.

In answer to a question from Dr. Eliot, he stated that no other cause for the convulsions than the placenta in utero was found in the case cited, there being no uræmic poisoning discoverable. The patient subsequently recovered.

DR. ROGERS believed with Dr. Sayre that the result of the case proved conclusively the cause of the convulsions.

DR. POST, in reference to Dr. Sayre's first case of cancer of sigmoid flexure, remarked that he had a brother who died at the age of twenty-nine years, who had no passage from the bowels for a period of nearly three weeks.

INFLAMMATION OF THE COLON AND OTHER CONSEQUENCES OF ARTIFICIAL NURSING.

Dr. Lewis Smith exhibited a specimen of inflammation of colon removed from the body of an infant who died at the age of one year and six months. This history was briefly told: The child was brought up by hand, and as is usually the case with such children, when the summer commenced it began to be affected with looseness of the bowels. The diarrhœa lasted through the months of July and August, and towards the last it was accompanied with the usual symptoms of progressive emaciation. About two weeks before the death of the child it became very drowsy, and vomiting, which before had only been occasional, now became more frequent. Death occurred from the comatose state in part, but mostly from exhaustion. At the time of death the emaciation was not marked. The evacuations during the sickness, according to the statement of the physician in attendance, were of a brownish or yellowish-brown color. There was never any discharge of blood.

On making the post-mortem examination the stomach was found in its normal state, the small intestine exhibiting here and there evidences of slight vascularity, but the mucous membrane of the large intestine was found remarkably thickened, roughened, and congested, as in colitis of the adult. This condition of things extended over the entire mucous membrane of that portion of the intestinal canal. There were no ulcerations.

On opening the thoracic cavity both lungs could be fully inflated, with the exception of a little nodule on the posterior aspect of the lower lobe of the right lung. The left lung could also be readily inflated, with the exception of the tongue-like process of the upper lobe and the lower margin of the inferior lobe. On examination of these parts, Dr. S. was of the opinion that their conditions were not due to pneumonia, but to a state of protracted collapse of the lung, continuing so long that it was impossible with the utmost force to inflate them.

On account of the prolonged drowsiness, it was of interest to ascertain the condition of the brain and meninges. That organ was normal in appearance, but the cavity of the arachnoid contained about four or five ounces of serum. There was also considerable effused fluid found in the lateral ventricles. The sinuses contained more than the usual number of clots, most of which were soft and red, while a few were white and quite firm, thereby giving evidence of their antemortem formation.

Dr. Smith, in conclusion, remarked that there were several points of interest in this case. The first had reference to the existence of such intense colitis and rectitis, without any evacuation of blood. He believed that in the colitis of the young infant this was not uncommon; in fact, Bouchout affirmed that dysentery was very rare in the young infant. The collapsed condition of the lungs at different points was another object of interest; and lastly, the condition of the brain being that of spurious hydrocephalus, deserved to be noted. In answer to a question from Dr. Rogers, he remarked that the fontanelles were depressed, as was commonly the case in all similar instances in very young children.

Dr. Rogers asked if the remark of Dr. Smith, in regard to the frequency with which children brought up by hand suffer from diarrhœa in the summer months, was amply borne out by facts.

Dr. Smith thought that as far as city children were concerned, it was.

Dr. Eliot remarked that there was one reason why it should be so, from the fact that the milk was most apt to spoil in hot weather.

Dr. Bibbins stated that among the lower classes the statement of Dr. Smith was especially true.

RUPTURE OF AORTA, PERICARDIUM, AND PLEURA.

Dr. Delafield exhibited a specimen of heart and annexa, taken from the body of a woman who was found dead in the street. She was apparently forty-five years of age, rather fat than otherwise, and various parts of her body and limbs were covered with bruises. There were no marks of violence about the head. No history was obtainable. On opening the chest the left pleural cavity was found filled with partially clotted blood. On the anterior surface of the pericardium there was a long rent through it, extending from the base almost to the apex of the sac; and on examining the heart itself, there was found in the aorta, just above the insertion of the aortic valves, a transverse rupture through all the coats of the vessel, surrounding which were several patches of atheroma. There were no changes in any other organs save the kidneys, the left one being loaded with small-sized cysts, and the right being in an advanced stage of fatty degeneration. The cause of death was, of course, a rupture of the aorta, the blood escaping first into the pericardium, and thence through the slit in that sac into the pleural cavity of that side.

GRANULAR KIDNEYS, ETC.

Dr. Finnell exhibited a pair of small granular kidneys taken from the body of a patient of Dr. Garrish, twenty years of age. She had been under the care of that gentleman two months previous to death. She presented during that period the usual symptoms of Bright's disease, severe headaches, vomitings, œdema of the face and extremities, etc. Her vision at times was so much disturbed by fatty degeneration of the retina, that she could scarcely see at all. The attending physician stated that the day before her death she was seized with a violent pain in the left side, attended with cough and dyspnœa. The diagnosis of pleuro-pneumonia was made and confirmed by Prof. Clark, who saw the patient in consultation. She gradually sank, and died the next morning.

The strange thing about the case was that at the autopsy no special lesion to account for death was found in the chest, and instead of pleuro-pneumonia, there was a simple œdema of both lungs.

A MUSEUM OF PATHOLOGY.

Dr. Finnell presented a second specimen on behalf of Dr. Leo, which also consisted of a pair of granular kidneys. These were removed from a man thirty years of age, who, being a driver on one of the city cars, was severely beaten by some rowdies, and died the following morning in Bellevue Hospital.

The post-mortem examination revealed such extensive disease in different parts of the body, that it became an interesting question whether the beating was the direct cause of death or not. There was cirrhosis of the liver, tubercles in the lungs, granular disease of the kidneys, and extensive extravasation of blood upon the surface of the brain, which had evidently found its way through the substance of the organ into the lateral ventricles. There were also present evidences of secondary syphilis. He had been a very hard drinker besides. Dr. F. thought it remarkable that a man with so much disease could be enabled to follow such an active occupation. He was of the opinion that death was caused by apoplexy, which had probably come on independent of the injuries.

GUNSHOT WOUND OF HEART AND LIVER.

A third specimen was also exhibited by the same gentleman, on behalf of Dr. Wooster Beach, Jr. It consisted of a gunshot wound of the heart, taken from a man who was accidentally shot in the pistol gallery of Barnum's Museum, while in a stooping position fixing the target. The ball entered to the right of the spine, fracturing the eleventh rib, passed through the liver, thence through the right ventricle at its lower portion, struck the sternum, and was lost. He walked twenty-five feet, and then fell dead.

He next presented a fourth specimen on behalf of Dr. Stirling. It consisted of the aorta with its principal branches, on the internal surfaces of which arteries were abundant deposits of atheroma. The remarkable circumstance was that the degeneration of the coats was principally confined to the posterior aspect of the vessels.

SOFTENING OF THE BRAIN—OBSTINATE CONSTIPATION.

He also exhibited, on behalf of the same gentleman, a specimen taken from a man sixty-five years of age, who five years before death became afflicted with softening of the brain, as evinced by a tottering gait and feeble intellectual powers The softening increased gradually, attended by paralysis, which was more or less extensive in different parts of the body. During the latter period of his illness he suffered from diarrhœa, which would alternate with long continued and obstinate constipation. At one time he was seventeen days without an evacuation, at another twenty-one, and at another thirty-five days. There was no obstruction of the gut to account for this. On examining the body after death the transverse and descending colon were loaded with large hardened masses of fæces, which being previously felt through the abdominal walls, gave the impression of internal tumors.

In answer to a question, Dr. Stirling remarked that the patient was an active business man, was in the habit of working his brain severely at times, and that during the thirty-five days of constipation he had no stercoraceous vomiting.

FIBRO-CARTILAGINOUS TUMORS OF EAR.

Dr. Post exhibited a fibro-cartilaginous tumor, which was remarkable on account of its seat, he having removed it from the helix of the ear of a mulatto, seven years old. It had been growing for three years. There did not seem to be any apparent cause for its appearance in that locality.

Dr. Sayre remarked that some years ago he had presented to the Society two such tumors, removed from the same positions from two different mulatto girls, caused in both instances by puncturing the ear for earrings.

The Society then adjourned.

Stated Meeting, September 25, 1867.

Dr. A. C. Post, Chairman *pro tem.*

Dr. Finnell presented the uterus and appendages of a woman twenty-five years of age, who died as the result of fallopian pregnancy. The patient was seen six hours after having been seized with violent abdominal pains, and when she was evidently in a dying condition. Her menstruation had been irregular, the last catamenia having occurred only two weeks before, which circumstance misled the doctor in making a diagnosis. She died twelve hours after the attack. At the autopsy the abdomen was found moderately filled with blood, about five pints in all. The left Fallopian tube was the seat of two enlargements; one, the smaller, nearest the uterus, was found ruptured on its proximal side; the other, larger, was situated in the fimbriated extremity, which was filled with apparently nothing more than a mass of coagulum. The left ovary contained a corpus luteum of recent formation. The uterus itself was but slightly enlarged. The patient had but one child five years before.

GUNSHOT WOUND OR FRACTURE OF THE BODY OF THE SECOND LUMBAR VERTEBRA.

Dr. Hamilton presented a conical rifle ball which he removed from a patient on the 18th of the present month at Bellevue Hospital. The case was as follows:

William Madden (enlisted as William McMahon), private 20th Conn., æt. 24, was wounded in battle, March 16, 1865, at Averysborough, N. C., the ball entering on the left side, a little above the crest of the ilium, and about four inches from the spine, and passing across deep and nearly horizontally to the right side, where it lodged. There was no evidence that any of the viscera of the abdomen were wounded. He fell immediately, and was carried to the rear, being unable to walk. There was no immediate paralysis of the bladder, but three days later a paralysis of the bladder existed to that degree that it became necessary to employ the catheter, and the urine had to be drawn for seven consecutive days. He was placed upon a water bed after a time, on account of bed sores. At the end of six months the ball was felt about four inches from the spine on the right side, but no attempt was made to remove it, probably because the diagnosis was not sufficiently positive. About one year from the time of injury he began to walk upon crutches; and about this time also, a small piece of bone escaped by the wound of entrance, containing a fragment of lead. Several other very small pieces escaped at other times. Three weeks ago, the position of the ball changed, falling lower down, so as to rest almost upon the crest of the ilium.

His condition before the operation, as stated by Dr. Hamilton, was briefly as follows: He was considerably emaciated, but well enough to walk about. The spinous processes of the first, second, and third lumbar vertebræ were unusually prominent, describing a curve backwards, such as we see in caries of the spine. They were fixed in this position; and the patient believes that no change in their form has taken place during the last two years. The wound of entrance was still open, and there were three other sinuses opening in the right groin, which evidently communicated with the first-named sinus. The bowels were tumid, tympanitic, and constipated. In making water there was often some delay, and generally some effort required to start it.

The ball could be distinctly felt in the situation before described.

The patient was placed under the influence of ether, and the ball exposed by a long and deep incision. It was easily removed by Dr. Hamilton, assisted by Dr. Pinkney, of the Bellevue Dispensary. He is now again walking about, and the discharge has much diminished.

The ball is flattened upon one side of its base, and at this point some small fragments of bone are embedded in its substance.

There are two points of interest in this case. *First*, that although the body of the vertebra was hit, there was no immediate paralysis of the bladder—the paralysis of the bladder taking place three days later, and no doubt as a consequence of the inflammation which ensued. *Second.* The case is of interest in that he has a fair prospect of complete recovery. It is quite cer-

tain that the lesion of the spine has been completely repaired long since; and there is every reason to believe that nothing but the presence of the ball has perpetuated the sinus.

In the Surgeon-General's report, Circular No. 6, one hundred and eighty-seven examples of gunshot fracture of the vertebræ are reported, of which one hundred and eighty died, and of the seven which recovered not one was a fracture of the *body* of a vertebra. There are collected in the Military Museum at Washington, sixty-six specimens of gunshot lesions of the spine and cord.

It is certainly very rare that patients recover after these accidents; but it must not be forgotten that one anatomical circumstance gives the patient some additional chances when any of the vertebræ below the first lumbar are hit in the adult.

In the child, at birth, the spinal cord extends as low down as the third lumbar vertebra, but in the adult no lower than the top of the second; here it terminates in a leash of nerves, which are firmer than the cord, and lying side by side in a common sheath, they slide upon each other, and do not probably suffer so often from concussion or compression. Mr. Alexander Shaw, to whom we are indebted for this explanation, has seen four examples of fracture of lumbar vertebræ below the second, unaccompanied by any degree of paralysis, and which were followed by speedy recovery.

Dr. Hamilton called attention to the fact that in this case the ball could not have struck the body very superficially, as in that case it must have wounded the vena cava, or the aorta, and it was probably an example in which the ball penetrated the centre of the side of the vertebra, making perhaps a round hole, of which several examples have been reported from time to time, or it may have passed in a deep groove, made on the anterior surface of the body of the vertebra.*

Dr. Post referred to a case that came under his notice at the Chesapeake Hospital, Fortress Monroe, in which a ball, after having traversed the soft tissues for a distance of nine inches, was very much flattened. The explanation for this seemingly extraordinary circumstance was, that the missile had, previous to entering the body of the patient, been flattened by striking against a tree.

CARIES OF THE TARSUS.

Dr. Kœhler exhibited a specimen of extensive caries of the tarsal bones necessitating amputation of the leg. The disease took its origin from an injury to the foot occasioned by a misstep into a hole, a year ago, since which time it gradually extended until it involved all the small bones of the ankle in destruction. Shortly after caries declared itself, a small portion of the os calcis, as well as of the astragalus, was removed with a view to arrest the progress of the disease, but the result was very unsatisfactory. There was a time when amputation at the ankle would have been practicable, but the patient refused then to have the operation performed, but subsequently, on account of the severe pain which the progress of the disease occasioned, he gladly consented to have the limb removed higher up. This operation was successful, and from last accounts the promises for recovery were good.

AN INTERESTING CASE OF ANEURISM.

Dr. O. H. Smith exhibited a specimen of aneurism, of which he gave the following account:

The patient was a seafaring man, forty-five years of age, who enjoyed good health up to a year ago, when he commenced to have pain in his chest, attended with cough and some dyspnœa. This condition of things increased, and at the end of seven or eight months from his first attack I saw him. He had previously been under the charge of another physician, and Professor Clark had seen him in consultation. Dr. Clark on his first visit was unable to say what he thought was the matter, but on the second visit he said that there was some enlargement of some of the vessels of the thorax, meaning aneurism. He advised tincture of aconite, evidently to control the heart's action. The physician had exhausted all his energies upon the case, and he being discouraged, I was requested to take charge of the patient. I found that he could lie only on his back, inclining a little to the right, bolstered up with pillows. Any effort on his part was sure to increase his difficulty in breathing, and even the mere swallowing of food would at times give rise to paroxysms of dyspnœa which were quite suffocative in character. He presented very much the appearance of a person in a perpetual paroxysm of severe asthma. His pulse in both wrists was soft and natural, and there was no increased pulsation in the arteries of the neck. On examining his chest nothing could be heard beyond the asthmatic breathing over every part of his thorax, and the dyspnœa was so great that he could not hold his breath that I might have an opportunity to listen to the heart sounds. The case looked to me like obstruction of the trachea either from within or without. There was no dulness over any part of the chest, but Dr. Clark had said it was aneurism, and I must accept the diagnosis although I could not see it. In the course of eight days after I saw him he sank and died.

The autopsy was made twelve hours after death. The lungs were found to be healthy. The trachea and surrounding parts were divided high up, with a view of turning out the whole viscera, when it was discovered that the aorta was firmly adherent to the spinal column. The parts were then more carefully examined *in situ*, when it was observed that the descending aorta, from the left subclavian down, was occupied by an aneurism about six inches long. The aorta was then forcibly torn from its attachments to the spinal column, when it was discovered that there was a groove along the spinal column upon its anterior surface; this groove was one-half or three-fourths of an inch in width, and from two to three inches in length. The aorta was attached to the spinal column on either side of this groove, the posterior wall of the artery having been obliterated by friction, or pressure of some kind. As this tumor was torn out, two large, firm, fibrinous clots were taken from it. These two clots occupied the anterior portion of the vessel, while the current of blood circulated behind, in the groove referred to. On further examination it was discovered that the ascending aorta, from the heart up to within half an inch of the innominata, was very much dilated and funnel-shaped. The descending aorta showed evidences of atheroma, and particularly upon the posterior aspect of the vessel. In the ascending aorta there were no signs of atheromatous deposit. The arch of the aorta, from the innominata to the left subclavian, was normal, which explains why there was no abnormal pulsation in the vessels of the neck, or of their branches. The œsophagus lay upon the right border of the spinal column from the arch of the aorta down, and the trachea rested upon the œsophagus. The trachea passed under the arch of the aorta, and the left bronchus passed over this tumor. The continual pressure of the tumor upon that left bronchus would explain the constant difficulty

* At the next meeting of the Society, October 9, 1867, the patient was himself brought into the presence of the members and examined, the diagnosis, as to the seat and character of the injury, being fully confirmed by all who were present.

of breathing. The patient died of asphyxia as do children with membranous croup.

Dr. Rogers moved that a committee be appointed to report on the specimen presented that evening by Dr. Finnell, which motion being carried, a committee of two, consisting of Drs. Rogers and Finnell, was named.

The Society then adjourned.

THE NEW YORK MEDICO-LEGAL SOCIETY.

Stated Meeting, October 8, 1867.

Dr. Thomas C. Finnell, President, in the Chair.

THE METHOD TO BE ADOPTED IN AUTOPSIES.

The points of discussion were taken up in the following order: notes, instruments, the surroundings of the body, the autopsy with the necessary concomitants of external inspection, examination of the head, thorax and abdomen, spine and limbs.

For notes, it was recommended that paper with printed heads be used referring to the information required. Time of commencing must always be stated.

The instruments should be as few as possible. Those generally employed were recommended, excepting the mallet and chisel. The best needle is the ordinary sail-maker's needle, sold at a trifling cost at all hardware stores. Its edges should be ground sharp.

In criminal cases, the various objects near the body should be examined with great care and their position entered in the notes. Too great caution cannot be exercised.

In the external examination, the body should be viewed from head to foot. Sugillation, and all other marks must be noted. The position of the limbs must be carefully observed; also the amount of decomposition and abdominal swelling. The location of the marks, etc., must be described by actual measurement.

In opening the head, the use of the mallet and chisel was objected to by some, as a fracture of the skull might result from their employment, where none existed before. To retain the skull-cap in place, Dr. Finnell's method of driving French nails far enough into the diploë of the stationary portion at the occipital bone to hold securely, then bending them so as to prevent the movable portion from sliding backwards, was explained; and also Dr. W. Beach's plan, consisting of a wire bent into loops, opening in contrary directions, in which the upper and lower cut sections were placed and held in position. Both these contrivances were intended to hold the bone in place, and prevent the unsightly mark in the forehead, where the edges do not approximate. A method to accomplish the same object was used by Dr. J. Beach. The line taken by the saw anteriorly, ran just over the forehead, the mark being hid by the hair.

To inspect the chest and abdomen, an incision from behind the symphysis of the maxillary bone to the symphysis pubis, was advocated, allowing the tongue, and contents of the neck and thorax, to be turned out. The disfigurement caused by this mode was thought sufficient, by some members, to prevent its general adoption. To lessen the flow of blood in taking out the heart, placing ligatures on the cavæ was suggested. Dr. Finnell illustrated his method of opening the heart, by which both sides of the organ were completely exposed. A number of valuable practical suggestions in this branch of the subject were made, but our space will not admit of further detail.

London Mud.—Thirteen per cent. of the mud in London is said to be abraded iron.

Correspondence.

THE QUESTION OF PRIORITY.

To the Editor of the Medical Record.

Sir—In the absence in Europe of my partner, Dr. Charles F. Taylor, will you allow me a small space in the Record for the publication of a few words in regard to the "question of priority" between Drs. Sayre and Taylor, as to the invention and use of a short splint in the treatment of hip-disease?

If I understand the matter, Dr. Sayre has raised a false issue, both in his letter of July 24, 1861, published in the *American Medical Times*, and in the one just published in the last number of the Record.

I understand Dr. Taylor's claim to be this, viz.: That he (Dr. T.) first devised and used a splint *with a cross-piece and joint at the top*, and with a *branch* to take the adhesive straps from the *inside* of the thigh. These peculiarities, which constitute the distinctive features of that splint, Dr. Sayre has adopted; the instrument has been labelled as "Sayre's," and, if we mistake not, Dr. S. has figured it in a published article as his own.

As to Dr. Taylor having "promised to publish a correction" of his "error," I can safely leave it for him (Dr. T.) to explain, on his return from abroad.

Respectfully yours,

W. E. Vermilye.

1808 Broadway, Oct. 4, 1867.

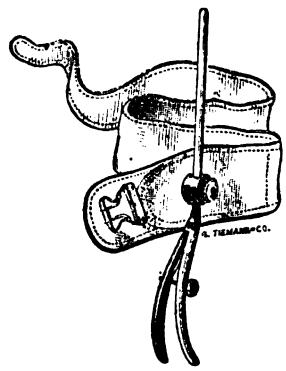
New Instruments.

EUSTACHIAN CATHETER HOLDER.

By O. D. POMEROY, M.D.,

new york.

The accompanying cut represents an instrument for holding the eustachian catheter in position, which may involve some principles of construction not often observed.



The band passing around the head and fastening the instrument to the forehead, is made of leather, instead of elastic material, to hold more firmly, as any giving is contra-indicated. The clamp which holds the catheter by means of a small thumb screw, passes vertically through a round aperture in a small post, placed at right angles to the forehead plate (of iron), which allows it to slide up and down through a circular aperture, which permits the clamp to revolve upon its axis; the whole fastened by a screw at the top of the post. Within the iron plate the post is fastened with a pivot-like arrangement, which allows the clamp to be moved from one nostril to the other.

In the cut the clamp is pushed so far up as to be above the level of the catheter. When adjusted, we have only to loosen the screw in the forehead piece, and allow it to drop down sufficiently to catch the catheter, when both screws are tightened. The advantage of this instrument over some others is—the ball and socket-joint at the forehead, which is easily worn out, and does never hold the catheter so as to perfectly prevent any antero-posterior movements, is here dispensed with, and the lateral pivot-like movement which allows the clamp to swing to either nostril without any screw adjustment, is peculiar to this instrument alone, as far as I know.

Some object to the use of the catheter-holder in toto; but when we reflect on the ease with which the catheter is displaced, and the attendant pain, the necessitating an extra hand for its management (unless the operator is very skilful), and the difficulty of introducing the bougie through a movable catheter, it seems to me its value must be conceded.

Obituary.

PROFESSOR ROBERT WATTS, M.D.

NEW YORK.

Robert Watts, M.D., the widely known Professor of Anatomy in the College of Physicians and Surgeons, N. Y., whose death occurred at Paris, September 8th, was born August 31, 1812, upon what is now the site of St. John's College, Fordham, Westchester county, N. Y. Having graduated from Columbia College, N. Y., in 1831, he began his medical studies in the office of Professor Willard Parker, the while attending the schools in Pittsfield, Mass., and Woodstock, Vt. Subsequently, however, he became the pupil of Professor Alexander H. Stevens in New York, and finally received his diploma from the College of Physicians and Surgeons, in 1835.

Dr. Watts early evinced a preference for the study of anatomy; and the proficiency which was the natural result of his zeal, well qualified him while yet a student for the duties of assistant to his preceptor, then Professor of Anatomy at the Woodstock College. After four years' service as Anatomical Professor at these Eastern institutions, he accepted, in 1839, a corresponding appointment in the College of Physicians and Surgeons, and from that date commenced his residence in our city. A resignation of his former positions in 1841 enabled him to devote himself more closely to the institution, of whose faculty he was at the time of his decease the oldest member.

In 1844, Dr. Watts, together with several other prominent physicians, took an active part in the foundation of the N. Y. Pathological Society, of which for several years he was the President. He was also a Fellow of the N. Y. Academy of Medicine, and a member of the N. Y. Medical and Surgical Society, as well as the Society for the Relief of Widows and Orphans of Medical Men, and the N. Y. Medical Journal Association.

The health of Professor Watts, which as a rule was rather delicate, at length became so much impaired at the close of the last collegiate session, that, in accordance with the advice of an intimate professional friend, who had detected tuberculous disease of the lungs, he concluded to test the advantage of a sea-voyage. During the latter part of May, therefore, in company with his wife, he set sail for England. Finding the climate of that region but ill adapted to his needs, he sought the more genial weather of the Continent. Here again he was disappointed, for his disease steadily progressed, and while in Paris, on August 30th, pneumo-thorax suddenly occurred. Under this he rapidly sank, closing his pure and gentle life with the crowning graces of Christian submission and patience, regretted by "troops of friends," and respected by all.

His remains were brought home, and after the funeral services held at the church of the Ascension, October 18, ult., were placed in the vault of St. Mark's P. E. Church.

New Publications.

Books and Pamphlets Received.

Injuries of the Eye, Orbit, and Eyelids, their immediate and remote effects. By Geo. Lawson, F.R.C.S., Eng., Assistant Surgeon to the Royal London Ophthalmic Hospital, Moorfields, and to the Middlesex Hospital; late Assistant Surgeon Rifle Brigade. London: Longmans, Green & Co. 1867.—(*From the Author.*)

Circular No. 7, War Department, Surgeon-General's Office, Washington, D.C., July 1, 1867. A Report on Amputations at the Hip Joint, in Military Surgery.

Inhalation, its Therapeutics and Practice. A Treatise on the Inhalation of Gases, Vapors, Nebulized Fluids, and Powders, including a description of the apparatus employed, and a record of numerous experiments, etc., etc. By J. Solis Cohen, M.D. Philadelphia: Lindsay & Blakiston. 1867.

A Contribution to the History of the Hip-Joint Operations performed during the late Civil War; being the Statistics of 20 cases of Amputations and 13 Resections at this articulation in the Southern Service. By Paul F. Eve, M.D., Prof. of Surgery in the University of Nashville, Tenn.

Transactions of the Medical Society of the State of Pennsylvania, at its 18th Annual Session. Fourth Series. Part III. Phila. 1867.

Synopsis of a Course of Lectures on Materia Medica and Pharmacy, Delivered in the University of Pennsylvania; with five lectures on the Modus Operandi of Medicines. By Joseph Carson, M.D. Fourth edition revised. Phila.: H. C. Lea. 1867.

The Practice of Medicine and Surgery applied to the Diseases and Accidents incident to Women. By Wm. H. Byford, A.M., M.D., Prof. of Obstetrics and Diseases of Women and Children, Chicago Medical College. Phila.: Lindsay & Blakiston. 1867.

Headaches, Their Causes and their Cure. By Henry G. Wright, M.D., F.R.C.S.L., L.S.A., etc. From the Fourth London Edition. Phila.: Lindsay & Blakiston. 1867.

Medical Items and News.

New York State Woman's Hospital.—The first portion, or one of the four quadrangular pavilions of the New York State Woman's Hospital, situate at the corner of Fiftieth street and Fourth avenue, was opened October 10th with very interesting exercises. The attendance of ladies was unusually large, and comprised a goodly number of those who are known throughout the city for their philanthropic works.

The Hon. James W. Beekman, President of the Board of Governors, presided.

After prayer by Rev. C. D. Foss, and a brief address by Mr. Beekman, in which a history of the institution was successfully reviewed, an address was delivered by

Dr. Barker, who said he was the only physician now living in the city who was thoroughly acquainted with the early history of the institution. He knew the zeal with which the profession welcomed the discovery that a surgical disease of the most distressing character, which the resources of art had heretofore failed to reach, was now by the genius and skill of Dr. Sims radically cured by one or more operations. It was evident soon after this discovery was made, that a special hospital was necessary to render available its benefits to a great majority of those requiring the operation. The Woman's Hospital Association was founded in February, 1855, with a Board of Managers consisting of thirty-four ladies. It is the work of woman for the benefit of woman. The hospital was opened on the 4th of May, 1855, with forty beds, and during the twelve years that have elapsed since that time over 400 cases have been cured of the most loathsome infirmity that woman is ever called upon to bear, by which she is debarred from all society, and made a burden to herself, and an infirmity which before was, as a rule, incurable. Within twelve years too, 1,219 cases have been discharged, cured or greatly relieved. New York City could point with proud satisfaction to the institutions which she now possesses for the relief of human suffering. The speaker here made mention of the various charitable medical institutions in the city, and spoke of the advantages they offered to the public. In again referring to the New York State Woman's Hospital, he said that not many years hence this beautiful edifice, which may now be said to be on the outskirts of the city, will be near the centre of a most prosperous and wealthy population. Who could estimate the incalculable amount of relief to human suffering which this institution is destined to afford—the number of desolate and loathsome wives, or wretched and helpless mothers, who will be restored to health and happiness? Dr. Barker next paid a feeling compliment to the surgeon in charge of the institute, and ended his address with an expression of confidence in the success of the good work thus begun.

Rev. Dr. Adams next addressed the meeting. He said he never envied Dr. Sims, but he did rejoice in the thought of the deep delight which Dr. Sims and his associates must have felt in the marvellous success which attended their efforts.

Short addresses were also made by Dr. Afred C. Post and Rev. Dr. Duryea, after which prayer was offered by Rev. Dr. Adams. The exercises were closed with singing and the benediction.

The edifice is on the French pavilion plan, and when completed will consist of a principal building on the centre of the flat, and connected with four pavilions built in quadrangular form by a series of corridors. The style is that known as the Lombardo-Italian. The exterior material of the walls is Philadelphia pressed brick, with a basement dressing of cut stone. The building will be covered in with a Mansard roof of ornamental slate, with ornamental ridge ornaments.

The main building is 160 feet in length by 40 in breadth. The first floor, intended for private paying patients, contains reception-rooms and sleeping apartments, fitted up with every requisite for comfort and convenience. The upper floors are devoted to sick wards, and are supplied with ample accommodations in the way of closets, bath-rooms, etc. On the third story is the operating-room, which is overlooked by a gallery intended for medical students. An elevator, worked by the engine of the laundry, supplies facilities for ascending to and descending from the upper portions of the edifice. Adjoining the main building is the laundry. In the basement are located two powerful steam boilers and a steam pump for heating purposes. On the upper floor are the washing-machines, capable of washing 2,000 pieces per diem, an elaborate mangling-machine, and the drying-room.

The State appropriated $50,000 toward the erection of the institution, and the city donated the site, and will in future have the right to nominate, free of charge, to one-fourth of the beds in the institution.

Though the institution will be in part self-supporting, yet it will in great part depend upon voluntary contributions. Its predecessor, the Woman's Hospital Association, numbered among its patients ladies who came from Europe for treatment.

Officers of the Medico-Legal Society.—At the late election the following were elected officers of the Medico-Legal Society: Dr. Thomas C. Finnell, President; Dr. Robert Newman, Vice-President; Dr. Simeon N. Leo, Secretary; and Dr. Augustus Wohlfarth, Treasurer.

The Zouave Jacob.—The Paris correspondent of the *N. Y. World*, after discoursing somewhat at length upon the achievements of the miracle-working Zouave, says: "General Forey was treated by Jacob after his usual fashion—that is, by a simple word of command—'Walk, because I say you can walk.' But the General himself has been too long accustomed to command to submit to the authority of a mere soldier, even if his palsied limbs were not past remedy. Jacob says that his failure in the General's case, and in many others, is not his fault; that he does not know the source of his power—pretend to discuss it, he only knows that he frequently brings relief when other remedies fail, and that he is willing to make use of his gift whenever he is asked. If he succeeds he is happy, if he fails he can only regret it. While Jacob's star was at its zenith, some new evidence of his miraculous power was published almost every day; now that it is on the wane, there is abundance of testimony against the authenticity of his cures. A story is told of a priest who, deprived of sight through a paralysis of the optic nerve, called upon the Zouave. 'Take off your spectacles,' said Jacob, 'and look me in the face. You can see!' 'No.' "But I say yes.' 'Well, then, yes.' And the ecclesiastic retired, to the great astonishment of the crowd. 'Your sight is improved, then?' said a friend to him as he was passing. 'Not in the least.' 'But please to explain.' 'Why, the fact is I did not wish to appear more stupid than the rest.'"

Medical Society of the County of New York.—Sixty-Second Anniversary.—This ancient society, which now numbers upwards of 250 members, celebrated its sixty-second anniversary, on the 21st ult., at the new Music Hall, corner of Houston and Mott streets. with a collation—nominally such—but, in its appointments and enjoyableness, really a dinner. The affair was decidedly a success; the reunion of the profession being both cordial and general. Speeches were made by Drs. Wm. W Reese, President of the Medical Society of the County of Kings; C. L. Mitchell, a delegate from that society to the State Medical Society; Edmund S. F. Arnold, President of the Medical Society of the County of Westchester; P. Stewart, of Peekskill; J. Foster Jenkins, of Yonkers; Eleazar Parmelee, President of the College of Dentistry; Alfred C. Post, President of the New York Academy of Medicine; James Knight, of the New York Society for the Relief of the Ruptured and Crippled; Professor Wm. Detmold, Dr. John P. Garrish, and Dr. Ellsworth Eliot. Excellent music enlivened the programme, and after "Auld Lang Syne," by the whole company, the guests reluctantly dispersed at a late hour.

THE NEW COLORED ORPHAN ASYLUM.—At the corner of 143d street and Tenth avenue, a new colored orphan asylum, to replace the building destroyed during the draft riots, is being erected. The style will be extremely simple, but the building will be very commodious and extensive. The dimensions of the main structure, which is to be built with all the modern improvements, are to be 234 by 100 feet.

THE NEW INFANTS' HOSPITAL OF RANDALL'S ISLAND.—It is proposed to build a new Infants' Hospital on Randall's Island. The building will cost from $100,000 to $150,000. The plans are now in the hands of Mr. Renwick, the architect, for his report.

THE INSTITUTION FOR THE BLIND in this city has one hundred and twenty-two students, half of whom are females.

THE NEW OFFICES OF THE COMMISSIONERS OF CHARITIES AND CORRECTION.—The site of new offices for the Department has been secured on the north-west corner of Third avenue and Eleventh street for $62,500—77½ feet by 100 feet in dimensions. The rooms on Bond street now rented by the Commissioners have long been ill suited for the purposes designed.

THE RELATIVE PROPORTION OF THE MEDICAL TO THE LEGAL PRACTITIONERS IN ENGLAND AND PRUSSIA.—According to a statistical article in an English paper, the number of lawyers in England is just about equal to the number of doctors, but in Prussia the doctors are nearly four times as numerous as the lawyers.

THE OPENING OF THE COLLEGES.—The College of Physicians and Surgeons inaugurated their regular season by the usual exercises, October 14th, ult. Dr. H. B. Sands, who succeeds to the chair of Anatomy, delivered the address, in which he alluded in a touching manner to the many virtues of Professor Watts, the late incumbent, and the Bellevue Hospital Medical College commenced its course with an interesting address by Prof. Frank H. Hamilton.

The University Medical College also formally opened their fall and winter course on the same evening, Profes or A. L. Loomis delivering an entertaining discourse upon the "Progress of Medical Science." The New York College of Veterinary Surgeons have likewise entered upon their duties. Professor F. D. Weisse addressed the friends of the institution assembled by invitation at the rooms of the New York Historical Society, October 2. He urged in warm terms the importance of a more thorough and extended knowledge of veterinary science. The New York College of Dentistry commenced their session October 15. Dr. J. Smith Dodge delivered the introductory address at the College in Fifth avenue, near twenty-second street.

DR. JOHN BETTS MCEWEN, of this city, died October 7 ult., of rupture of the heart consequent upon fatty degeneration, aged 59 years. He was a graduate of the College of Physicians and Surgeons, class 1831.

A NEW WORK.—Darwin, whose "Origin of the Species" created somewhat of a sensation in the scientific world, has a new book in press, entitled, "The Variation of Animals and Plants under Domestication." The work, which will elucidate the principles of inheritance, reversion, crossing, interbreeding, and selection, will be published by Murray, of London, and will consist of two octavo volumes.

RARE MODESTY.—A gentleman who refuses to have his name published, has donated to the Birmingham (England) General Hospital $50,000.

OPIUM EATING IN ENGLAND.—Dr. Hawkins, of King's Lynn, tells the readers of the *Medical Journal* that half the opium imported into England is consumed in Lincolnshire and Norfolk. One Lynn chemist sells 200 pounds, another 140 pounds a year of solid opium, besides five or six gallons of laudanum, and five or six gallons of "Godfrey's Elixir" (a pint of laudanum in every three gallons) a week. People will be startled to hear of drawers full of half-drachm packets of opium, of which many customers take three a day. A farmer came in to get some good laudanum. "How many drops?" asked the chemist. "Drops?" was the reply; "give me an ounce and a half." The chemist looked at him, saw he was in the habit of taking it, and gave him the dose. He drank it off, returned twice in the day for the same quantity, and took home a half-pint bottleful with him when he left market. The habit is no new one. The present writer can vouch for its existence in and around Spaulding, and even across in Leicestershire a dozen years ago. The excuses would be obvious—deficient food with the poor, ague and "rheumatiz." needing an anodyne, with others. But it is a growing habit, and Dr. Hawkins speaks very strongly of its pernicious effects in poisoning the blood. To it he attributes the excessive infant mortality in the district, and the "miserable, feeble, brownish-yellowish countenances so striking among many of the inhabitants." In fact, he thinks its effects on the system almost as bad as those of syphilis, and calls for some interference to discourage what is becoming a cause of wide-spread degeneracy in the breed.—*Imperial Review.*

MULTIPLICITY OF CHINESE REMEDIES.—The great strength of Chinese medicine lies in the multitude of their remedies. Their materia-medica is as large as ours. It consists of a vast accumulation of materials that, age after age, empirics have said were good for this and good for that. Of such facts their books consist. They are characterized by a vast predominance of vegetable matters. As a science they know nothing of botany; but as far as acquaintance with the characteristics of the plants goes, their growth, and properties when used as medicines, they are exceedingly well versed. I might say with safety, that every plant that grows in China has been studied with a view to its medicinal qualities, and, no doubt, they are in possession of valuable facts that will in time be made useful in other countries; and I might say also, that they are about as successful in the treatment of diseases as physicians in other countries. Next to vegetable remedies are animal products in their practice. Some of them are exceedingly disgusting in their application to the human system. The more outlandish the animal the better is the medicine. The medicine taken from a shark, for instance, is considered more powerful than that obtained from a better disposed fish; and the blood of a lion or tiger is more cheerful as a medicine than the blood of less ferocious animals. The blood of a tiger would be given to a man who needed a little more of the tiger in his composition; and the blood of a lion would be given to one who needed a general rousing up of his powers. A class of medicines which we have not touched as yet, is the poisonous substances of animals and insects. They do not know how to extract the poisons, but they cut off the stinging portions of insects, scorpions, and such like, which are prized very highly, and apply them in various ways. Some of them prove very powerful and prompt in their action. They do not deal very extensively in mineral substances, arguing that as but few of the mineral substances are embraced in the human organization, it would not be proper to infuse such substances into the system. Mercury and iron are about the only minerals they use, which they employ in various forms,

mercury extensively, in something like our blue pill, and some resembling calomel.—Dr. Wiley, *Cinn. Lancet and Observer.*

Hudson County, N. J., Medical Society.—This Society held its regular monthly meeting on Oct. 1st, nine of the members being present.

The committee appointed at the last meeting to examine and report upon existing laws of the State with reference to the practice of medicine, made their report recommending that the subject be urged upon the attention of the State Society at its next annual meeting.

Dr. Culver related the history of a singular and fatal case of choleraic dysentery, supposed to have originated from the noxious gases generated by an animal in a state of decomposition. Dr. Varick reported a very rare case of complete lateral dislocation of the elbow-joint. Dr. Chabert exhibited a specimen of tænia lata eleven feet in length, entire, expelled from a patient by the use of three capsules of Dipple's animal oil.

The Salt Springs of New York produce nearly 7,000,000 bushels of salt per year.

Cinnabar in California.—An exceedingly rich bed of cinnabar has been discovered about four miles south of San Jose, Cal. There is a solid ledge about twelve feet wide and eight feet thick, between walls of rock, which grows richer as the excavation proceeds.

The so-called Natural Soap of Missouri.—Natural soap, it is again announced, has been discovered in Missouri, some sixty miles from St. Louis. What has been really found is probably "fuller's earth," a variety of clay which, from its unctuous touch, might easily be mistaken for soap.

The Dangers of Boat Racing.—The *Lancet* thus speaks of "The Dangers of Boat Racing": Few laymen have the slightest idea of the dangers to which a supreme physical struggle, like the finish of a University boat-race, subjects organisms * * * * * * * We sincerely trust that the fine young fellows, whose exertions at the race have incidentally occasioned our remarks, will sustain no lasting harm from their efforts; but we think it our duty to inform them, and the whole race of crack oarsmen, of the almost inevitable consequences which would arise from even a few repetitions of such a performance. It unfortunately happens that the experience of medical men in this matter has never been published in a complete and compendious form; but there are few London physicians who have not met with lamentable illustrations of the mischief done in this way. The tremendous respiratory efforts which a fatigued man must make when he puts on such a series of spurts as those which Cambridge made, very often produce rupture of the air-cells of the lung, and a dangerous permanent emphysema. The furious action of the heart *may* cause rupture of a valve, and very frequently *does* cause cardiac dilatation, with or without hypertrophy, and lastly, the enormous blood pressure in the vessels is not uncommonly the cause of aneurism. Exact statistics are wanting on the subject of these maladies as thus produced, nor can we say accurately to what extent they shorten life; but it is certain that men who have committed great excesses in taxing their powers by boat-racing when young, frequently do not survive to old age. We have known of several deaths from fatty and dilated heart, quite in early middle life, which were directly traceable to this cause. The dangers incidental to the process of training, and the climax for which it is the preparation, are best avoided by the selection of men of sound *physique*, by a gradual education for the contest, and by the avoidance of an abrupt subsequent transition to ordinary habits of life.

The Humboldt Medical Archives.—The first number comes to us in a very creditable shape, and contains original communications, an interesting lecture by Prof. Hammer, editorials and news. It is under the editorial charge of Drs. A. Hammer and M. A. Pallen, they having for co-editors the faculty of the Humboldt Medical College, St. Louis. Although emanating from the said college, the intention is to make it cosmopolitan, but this is not made as apparent as it might be if an elaborately written editorial notice of the advantages of the institution were omitted.

Work on Military Surgery.—The *Gazette Médicale*, of Paris, speaks well of a work called "Military Surgery in France and America," by M. Goze, and which, it seems, exhibits a comparison very favorable to the American military surgical appliances, and of the sanitary department generally of the U. S. government.

American Ambulances.—The Paris correspondent of the *London Medical Times and Gazette*, and also that of the *Illustrated News*, calls the American ambulances the best in the Exhibition, and the one exhibited by Dr. Benjamin Howard, of New York, the most perfect of them all. The "Times and Gazette" correspondent, deems it a matter of regret that Dr. Howard's ambulance was not known until nearly the close of the war.

A Medical Cannibal.—The *Liverpool Post*, of the 16th Sept., announces the extraordinary fact of a medical assistant actually cooking and dining off of a corpse. This disgusting affair took place at St. Thomas's Hospital, London. As a just punishment for such an outrage upon common decency, the medical authorities have publicly dismissed the would-be cannibal in disgrace.

Another Death from Chloroform.—Deaths from chloroform are now getting to be so common that it requires a faithful chronicler to keep track of them. The present case occurred (so says the *Liverpool Post*) at the Northern Hospital, Liverpool, on the 11th of Sept. The operation to be performed was that of straightening an anchylosed knee, the result of a fracture received some time previously. The junior house-surgeon (Mr. Trubshaw) administered chloroform by means of Skinner's inhaler, using about four or five drachms, and thinking that the deceased would not inhale more than half that quantity. Deceased exhibited alarming symptoms towards the close of the operation, and artificial means were employed to sustain respiration, but he expired shortly afterwards. The chloroform, it appeared from the evidence, was carefully administered, and every precaution used to prevent misadventure. A post-mortem examination of the body was made by Dr. Wollaston, senior house-surgeon at the hospital, and his opinion was that death resulted from syncope induced by chloroform. He added that the medical gentlemen present at the operation were satisfied with the manner in which the chloroform had been administered. Verdict, "Died from misadventure, from the administration of chloroform, during an operation." The jury added, that no blame was attachable to any of the medical gentlemen, and that the chloroform had been administered with caution. The patient was fifteen years of age.

A Permanent Anæsthetic Wanted.—A reward of $10,000 has been offered by an English gentleman, through the chairman of the London Hospital, to any person who shall have discovered by July 1, 1868, any means by which in all, or nearly all cases, pain can be both

permanently and completely extinguished, as it can now be extinguished for a short time.

Longevity of Brain Workers.—Reasoning from analogy and from the facts of biography, it would seem that those who are endowed with unusual intellectual powers can work harder and longer, all things being equal, than the rank and file of humanity. The law is that great intellects are incased in sturdy, powerful frames, and the occasional existence of monstrosities serves but to establish the rule. The number of really great men of history is comparatively so small that it is impossible to fully substantiate this theory by statistical facts, but if we take the record of biography from the earliest time to the present as our guide, it would seem to be very clear that intellectual giants are capable of undergoing severer brain labor, with far better prospects of longevity, than men of mere ordinary ability. I have taken the pains to go through the cyclopædia, and to note down the ages of *one hundred* of the greatest men of history, those who have created epochs, and have been the leaders of the world's thought in literature, art, science, and statesmanship, and I have found that the average age of these was much higher than that of literary and professional men generally; nay, even much higher than that of clergymen, the longest livers of all. This list, which covers a period of many centuries, contains such names as Goethe, Coleridge, Lessing, Beranger, Wordsworth, Voltaire, Hume, Milton, Shakespeare, Dante, and Irving, among men of letters; Raphael, Michael Angelo, and Reynolds, among painters; Malebranche, Locke, Leibnitz, Kant, Hobbes, and Hamilton, among modern philosophers; and Socrates, Aristotle, Plato, Cicero, among the ancients; Harvey, Cuvier, Buffon, Galileo, Humboldt, Newton, Jenner, and Faraday, among men of science; Napoleon, Marlborough, Washington, Metternich, Richelieu, Burke, Webster, Calhoun, and Clay, among warriors and statesmen; and Calvin, Luther, Knox, Butler, Paley, and Edwards, among theologians. No one will deny that these and similar names fairly represent the giants of history.—*Geo. M. Beard, M.D., in "Hours at Home."*

Death from Chlorodyne.—On Saturday last considerable excitement was created in the town of Harleston by the report that a woman named Elizabeth Saunders had been poisoned by chlorodyne. The deceased has for several years been in the employ of Mr. Thomas S. Stanton, of Mendham, who supplied this town with milk. While on her round with the milk on Saturday morning, she called on Mrs. Arnold, and as she complained to her that she was suffering from diarrhœa, Mrs. Arnold gave her a dose of chlorodyne, which had as she thought been prepared for her son, but which it turned out was undiluted. On discovering her mistake, Mrs. Arnold sent for Saunders, and gave her some antimony as an antidote. She was, however, left to go on her way, and not returning home at her usual time, inquiry was made for her, and she was found, between 10 and 11 o'clock, in a water-closet in the town, in a state of unconsciousness. Medical attendance was called in, and every attention was shown her, but she never rallied, and only lingered till 10 o'clock at night. An inquest was held on Monday morning, when a verdict of "Accidental death from an overdose of chlorodyne" was returned.—*London News.*

Extensive Examination of the Eyes.—A curious work has been published at Breslau lately by Dr. Hermann Cohn, giving the result of an examination of the eyes of 10,060 school children. The proportion of short-sighted children was 17·1 per cent., or 1,730 among 10,060. No village children were found to be short-sighted until they had been some time at school—at least half a year. Dr. Cohn attributes the evil in a great measure to the bad construction of school benches, which force the children to read with their books close before their eyes and with their heads held downwards. The obstinate adherence to the ancient Gothic character in printing and writing, to which Englishmen are generally inclined to attribute the prevailing near-sightedness of Germans, is not alluded to by Dr. Cohn.

Suicides in England.—The Registrar-General has published a curious return of the number of suicides in England during the eight years from 1858 to 1865. They average 1,300 annually, and to every million of the population run thus in each successive year: 66, 64, 70, 68, 65, 66, 64 and 67. Hanging has always been the death generally adopted by suicides, 28 out of the ratio of 67 per million suicides falling under this head. After hanging follow cutting, stabbing or drowning, poisoning, and by firearms. The ratio of suicides per million of the respective populations in 1864, was 110 in France, 64 in England, 45 in Belgium, 30 in Italy, and 15 in Spain.

The Washington University—A New School of Medicine.—A new medical institution under the above name, having a corps of professors second, perhaps, to that of no other institution in the country, is about being established in Baltimore, under auspices which lead to the assurance of its permanent success. There is no doubt that Baltimore, regarded as a favorable point for education generally, may find abundant support for more than one medical school, and with that idea this project has been commenced.

The regular sessions of Washington University will begin annually on the first Tuesday in October, and continue for five months. A summer course of lectures, beginning on the first Monday in April and concluding on the last day of July of each year, will be delivered by the adjunct faculty. The faculty consists of the following professors: Rev. Thomas E. Bond, M.D., President; G. C. M. Roberts, M.D., Emeritus Professor of Obstetrics, and Diseases of Women and Children; C. L. Ford, M.D., Professor of Descriptive and Surgical Anatomy; J. P. Logan, M.D., Professor of the Principles and Practice of Medicine; Harvey L. Byrd, M.D., Professor of Obstetrics; Martin P. Scott, M.D., Professor of the Diseases of Women and Children; Edward Warren, M.D., Professor of the Principles and Practice of Surgery; John F. Monmonier, M.D., Professor of Physiology and General Pathology; J. J. Moorman, M.D., Professor of Medical Jurisprudence and Hygiene; Joseph E. Clagett, M.D., Professor of Materia Medica and Therapeutics; Clarence Morfit, M.D., Professor of Medical Chemistry and Pharmacy; John N. Monnomier, M.D., Demonstrator of Anatomy.

The faculty have obtained an eligible location for the holding of lectures and cliniques in the large building corner of Calvett and Saratoga streets, where, during the session, daily classes will be held. It is intended by the faculty to obtain a permanent location at an early day. Added to the University is a free dispensary, recently opened at the University building, at which all persons desiring medicine or surgical attention are treated daily, between the hours of 12 M. and 1 P.M. During these hours both professional services and medicines are furnished gratuitously. The following are the surgeons and physicians of the dispensary: Surgeons—Profs. Edward Warren and C. L. Ford. Physicians—Profs. Joseph P. Logan, Harvey L. Byrd, John F. Monnomier, Joseph E. Clagett, and Martin P. Scott.

CASES OF
REFLEX AND ORGANIC PARALYSIS TREATED BY ELECTRICITY.

By A. D. ROCKWELL, M. D.,
AND
GEORGE M. BEARD, M.D.,
LECTURERS ON NERVOUS DISEASES IN THE UNIVERSITY MEDICAL COLLEGE OF NEW YORK.

FACIAL PARALYSIS TREATED BY THE GALVANIC CURRENT.

CASE I.—Miss P., a stout, vigorous young lady of fifteen, was sent to us by Dr. F. Elliott to be treated for paralysis of the seventh pair, on the left side, caused by exposure to a draught of air two months previous. The paralytic symptoms came on suddenly and in full force immediately after the exposure, and at first she experienced considerable difficulty in speaking.

She gradually became so accustomed to the abnormal condition of her lips and face that she was able to converse almost as clearly as before; but the improvement in the condition of the paralyzed muscles was very slow, and at the time she came to us the affection appeared to be almost stationary. At the time she received the first application at our hands (Aug. 1, 1862), she presented most of the usual symptoms of paralysis of the seventh pair.

Her mouth was drawn over towards the healthy side so violently as to produce considerable deformity when she laughed or conversed, and even when she smiled. When she attempted to frown, the left brow remained as smooth as that of a child.

Her left eye rolled up, and when she attempted to close it, the lids would not approach nearer than one-quarter of an inch to each other. A powerful Faradaic current, localized in the affected muscles, produced very feeble or imperfect contractions; while on the sound side, a very mild current applied with the hand, produced active contractions of all the principal muscles. The patient was so well in all other respects, that we decided to use only partial or localized electrization over all the muscles on the left side of the face. Two vigorous applications made in this way, one electrode being placed firmly below the ear, and the other passed over the ramifications of the seventh pair as well as over the individual muscles, did not seem to increase to any appreciable extent the electro-muscular contractility, and accordingly we resolved to adopt an entirely different method of warfare.

The next time we localized the galvanic stream through the left side of the face, and with most charming results. Contractions of the paralyzed muscles were at once produced that were as vigorous and as natural as those caused by the Faradaic current on the healthy side.

The patient began at once to improve, and after ten visits, distributed over a period of six weeks, she was dismissed as approximately cured. There still remained some deficiency of action of the muscles concerned in frowning and in winking, but the expression of her face, both in repose and in conversation, was normal. The very little that remains, nature ought to accomplish unaided. The interesting points are as follows:

First.—*The galvanic current produced contractions, and wrought a cure, when the induced or Faradaic utterly failed.* This important fact with regard to the galvanic current, viz., its power of causing contractions in paralyzed muscles that do not appear to be affected by the Faradaic was first pointed out by the late Prof. Remak, of Berlin, whose original and able researches in electro-therapeutics* really made him the father of a distinct school of electricians in Germany, as Duchenne has long been in France. Though the ideas advanced by Remak were at first scouted and despised by the profession, as, indeed, has ever been the case with all original suggestions in science, and although his own impetuosity and extravagance hurried him into generalizations that could not have stood the test of investigation, yet his leading idea in regard to the superiority of the galvanic over the Faradaic current, in some forms of paralysis, is now as fully established as any fact of science among those who are practically familiar with electro-therapeutics.

These observations of Remak have recently been confirmed in a very striking manner by Prof. Ziemssen,† of Berlin, by Schulz, Meyer,‡ Baierlacher, Neumann, and Hammond. As a rule, the benefit received in such cases is proportioned to the extent of the muscular contractions that can be produced. The current, either the Faradaic or the galvanic, acts as a *local tonic*, bringing into action the diseased muscular fibres, increasing the local processes of waste and repair, improving the circulation, and consequently making the parts permanently warmer and stronger. These results we have observed very markedly in a number of cases of infantile paralysis, under the influence of general electrization with the Faradaic current.

Second.—The paralyzed muscles were at first brought to contraction by a galvanic stream of small quantity, but of considerable intensity, *that had no effect whatever on the muscles of the healthy side.* As the patient improved, however, it became necessary to use a stronger galvanic stream in order to produce the contractions. Towards the close of the treatment, the muscles of the paralyzed side began to respond to the Faradaic current. These apparent inconsistencies had also been previously observed by a number of the German electricians already mentioned. The late P. Victor Bazire§ has recorded an experience almost precisely similar. It does not follow from these facts that the relative value of the two currents is entirely undecided. On the other hand, it may well be questioned whether we do not know nearly as much of the indications of their use and the rationale of the operation of their currents, as of any of the internal remedies that are styled specifics. In general electrization for the purpose of producing a constitutional tonic influence, in partial electrization with a view to calmative or absorbent effects, and for most cases of localized electrization, we use the Faradaic current.

On the other hand, for those exceptional cases of paralysis where the Faradaic current will not produce contractions, and also when it is desired to affect the retina, we use the galvanic.‖

Third.—Although the galvanic current applied to the face caused intense flashes of light, affecting the retina by reflex action, as is always the case when it touches any part supplied by the fifth pair, it yet was in no way injurious to the eye.

Long ago, Duchenne recorded a case of permanent blindness resulting from over-excitation of the retina through a strong galvanic stream applied to the face. The patient reported that the whole room seemed to be in a blaze, and immediately afterwards she became blind on the side to which the current had been ap-

‖ The galvanic stream appears in some instances to cause absorption more rapidly than the Faradaic. For its use in the form of galvano-cautery, *vide* Althaus on Tumors and other Surgical Diseases. London, 1861.

plied. This sad experience of Duchenne has had the effect of deterring the electricians of France, England, and America, from using the galvanic stream of any strength to the parts supplied by the fifth pair. But, with all deference to those who differ from us, we cannot regard this fear as well grounded. One case, if anything, proves but little in science, and there is at least reason for suspecting that the unfortunate patient of Duchenne was at the time affected by some weakness of the retina or other parts of the eye that prepared her for the final catastrophe.

Certain it is that the accident has never been repeated, so far as we know, by any of the recent experimenters in this department. On the other hand, very many of the German electricians use the galvanic stream, oftentimes from a large number of elements, in various affections of the face, and without injury. For ourselves, we never hesitate to employ the galvanic current of any strength so long as benefit may be received. More than that, we have tested the stream from a large number of elements, on our own faces, in order to experience its physiological effects on the salivary secretion, sense of taste, and always without injury. It may, indeed, cause a slight headache, dizziness, or drowsiness; but so may the Faradaic current, when used in excess or without proper caution. But facial paralysis may often be relieved by the Faradaic current alone.

PARTIAL PARALYSIS OF THE RIGHT SIDE OF THE FACE, WITH CONTRACTION OF MUSCLES, FOLLOWING NEURALGIA.

CASE II.—Miss J., aged forty, came to us in the early part of September of the present year, to be treated for a facial paralysis of a peculiar character. Her face was drawn to the right side, so that her features were very much distorted. We at first supposed, and very naturally, that the case was one of paralysis of the seventh pair of the left side, but a more careful examination led us to modify our diagnosis.

Her history was as follows: Several years previous, while occupied in day and night attendance at the bedside of a sick friend, she was suddenly attacked with severe facial neuralgia of the right side, that continued to annoy her for two months. The disease then abated, but since that time she has been frequently harassed by persistent numbness in the right arm and hand.

On localizing a strong Faradaic current through the muscles of the *left* side of the face, powerful contractions were excited. On the *right* side no such effect could be produced.

Furthermore, her right eye was nearly closed, owing to a partial ptosis, and while she could easily frown and corrugate the left brow, the right was entirely smooth and expressionless. It was very evident, both from the history of the case and from symptoms at the time, that the *right* side was paralyzed, and not the left, as at first appeared, and that the face was drawn towards the right by the contractions of the *muscles following the paralysis.*

The lamented Trousseau, whose lectures on clinical medicine are unrivalled, not only for their originality and suggestiveness, but also for clearness and fairness of statement, as well as for elegance and beauty of style, has described this condition so accurately that we quote his own language as it appears in the translation of Bazire.*

After relating the symptoms of a patient suffering from paralysis, he says: "If left facial paralysis was thought of at first sight, the depression of the lower lid, and the less marked expansion of the nostril on the right side, were already sufficient to cause a modification of the diagnosis. But when the patient attempted to move that side of her face there could no longer be any hesitation, and it became manifest that it was the right side which was affected. When she spoke, and still more when she laughed, her face was pulled with force to the left, the upper lip and the ala nasi on that side going obliquely upwards, and the labial commissure being drawn with considerable energy upwards and outwards. When she attempted to blow, her left cheek swelled, and her mouth remained closed on that side, whilst her right cheek was flaccid and her mouth opened out a little on that side. Besides, she could not shut her right eye, however much she tried." . . . . . .

In this case we used only the Faradaic current, localizing the electricity as nearly as possible along the course of the portio dura and its ramifications. To accomplish this the small positive electrode was pressed firmly under the right auricle, near the point where the nerve emerges from the temporal bone, while the negative was moved along its various terminal branches.

No particular results were obtained from the first application, but during the second visit slight contractions were produced on the right side, and it was then noticed that the eyelid did not fall so low as before.

In the course of a few days the patient again visited us, when the improvement was quite marked. There was considerable relaxation of the contracted muscles, and the electro-muscular contractility was readily demonstrated. At the fourth visit, which occurred about two weeks from the commencement of treatment, the ptosis was hardly noticeable, and the power of corrugating the occipito-frontalis on the right side was perfect. There still remained, however, some distortion of the features, owing to the obstinate nature of the muscular contractions, and, although she subsequently received quite a number of applications, the contraction was not so entirely dissipated as were all the other symptoms. But the amelioration was so complete that the distortion was little noticed, and ceased to give her any considerable annoyance.

CASE III., in its manifestations, was similar to the first case, not only as to its causation, but also in many of its symptoms. Its principal interest is derived from the fact that the Faradaic current caused contractions of considerable power in the muscles of the affected side, while in the other case the galvanic stream alone caused the muscles to respond to any extent. We made use of the Faradaic current on four different occasions, with the effect of benefiting the paralysis and markedly lessening the consequent distortion of the features.

About this time (three months previous to the date of this article) she was confined, and, as her home is some distance from the city, we have not seen her since. By direct information, however, we learn that her paralysis remains the same as when we last saw her. There is every reason to believe that an approximate cure would be effected by a few more applications.

CASE IV.—Mr. M. was brought to us by Dr. Cockroft to be treated for paralysis of both sides of face. In the month of March, 1862, during the retreat of the Confederate army from Kentucky, this gentleman, after prolonged exposure to cold and wet, was attacked with facial neuralgia. Previously he had been so unfortunate as to contract syphilis, which had passed into the secondary stage; but for several years he had been, to all appearances, entirely free from the disease. This attack of neuralgia was followed by partial paralysis of the right side of the face. The neuralgia persisted until July, but the paralysis has continued constant until the present time. In January, 1866, he had a renewal of the neuralgia, which this time attacked the left side of the face. It was of an intermittent type, and on the 25th of March, without a premonitory symp-

* Lectures on Clinical Medicine, Part II., p. 328.

tom, and when he was entirely free from pain, the left side of the face became completely paralyzed. He gradually lost the sense of hearing, and in two weeks was absolutely deaf. When brought to us for treatment he was suffering from paralysis of the whole face.

He was unable to close either eyelid, could neither elevate the eyebrows nor frown. He had but little control over the mouth, and, as a consequence, his speech was very imperfect. "The motionless face assumed a peculiar aspect, and looked like a lifeless mask, on which the impressions of the soul were no longer expressed but by changes of color." We had but little hope of benefiting him, nor were we disappointed; for after a month of faithful and hopeful perseverance on the part of the patient, not the slightest improvement was observed. For a little time after an application he seemed to possess more control over the muscles of the eye and mouth, and his articulation was evidently more distinct. Dr. Devaine gives, after Marshall Hall, the following test, by which it may be ascertained whether the cause of double facial paralysis is seated in the brain or in the course of the nerves: In the former case the conducting power of the nerve-trunks is retained for an indefinite period, so that by galvanizing the trunk and the principal branches of the facial nerves, all the muscles supplied by them are thrown into contraction, as if the muscles themselves are being galvanized, whilst, when the paralyzing cause is in the course of the nerves, they very easily lose their conducting power.

Moreover, if reflex movements be seen in the paralyzed muscles, it will be a sure evidence that the cause of the paralysis is in the nerve centres.

If the above test can be relied upon, and we are inclined to think that experience will prove it to be of great value, the seat of the trouble in the case under consideration was evidently in the course of the nerves. The strongest current that we were able to induce caused no contraction of any of the muscles of the face, and reflex movement was entirely absent. We had no opportunity to use the galvanic stream, much to our regret, since the case first related in this article proves that it is often of service when the Faradaic current is useless.

In this connection it may be proper to say a word in regard to the general indications that call for electrization in the various forms of paralysis.

It seems all the more important that we should make this explanation, from the fact that physicians who in many particulars are well informed and even advanced, appear to forget that paralysis is merely a *symptom* of some disturbance in the central nerve system or at some point of the nervous connection.

It needs then no demonstration to show that the curability of any given case of paralysis, whether it be hemiplegia, paraplegia, or facial, must depend on the cause. According to our experience with electrization in paralysis, the following points seem to be pretty clearly established:

1st. In hemiplegia, paraplegia, and glosso-laryngeal* paralysis (glosso-pharyngo-labialist), dependent on persistent, irritating, central lesions, such as softening of the brain, active tumors, local injuries, and the like, electrization in any form is sometimes contraindicated, or at least is of no positive value. It has been observed that patients affected with softening of the brain are very apt to suffer for a time after an application with a kind of quivering or tremor that is almost diagnostic.‡

2d. In paralysis dependent on lesions that are not persistent, either galvanization or Faradaization are usually of great benefit, and even though absolute cures are not always obtained, yet the process of fatty degeneration of the muscles may often be retarded and arrested, and in the majority of cases the power of motion and tactile sense can be greatly increased. These pleasant results are very markedly observed after persevering electrization of cases of *infantile* paralysis. But in all that we attempt for such long-standing affections of the nerve centres, we should ever keep in mind the emphatic words of Trousseau: "Chronic diseases demand chronic treatment."

3d. Paralyses that are not dependent on any form of central lesion, such as are variously termed reflex, peripheral, functional, anemic, or hysterical; also those of a traumatic origin, or those which are due to exposure to cold, *recent* cases of lead palsy, and the mysterious affection termed "writers' cramp," are very often absolutely and permanently curable by judicious, practical, and continuous electrization.

More than this, such cases, if taken early, are sometimes cured or relieved as promptly and as rapidly as any other class of affections with which we have to do. The conviction is every week being more and more forced upon us that, were such kind of paralytics submitted to proper electrization *at once* after the symptoms appear, the number of cripples would be greatly diminished.

In the course of these articles we shall present cases illustrative of nearly all these different types of paralysis, and shall detail the method, and results of treatment by Galvanization and Faradaization in these three classes: *First*, those that received no benefit whatever, or in which electrization was contraindicated. *Secondly*, those that were temporarily or permanently benefited. *Thirdly*, those that were absolutely or permanently cured.

But although this series of articles is to be mainly occupied with paralytic symptoms, we shall be very sorry to give the impression that paralysis is the only or, indeed, the most important affection for which electrization is indicated. In conversation with our friends in the profession the inquiry is continually made as to what we can do for paralysis; but great surprise is expressed when we reply that our most interesting and most uniform successes are with an entirely different class of nervous affections, and even with inflammatory states.

We cannot therefore too often repeat, in all our writings and teachings, that general electrization with the Faradaic current, using the hand as an electrode, is a tonic of wide and varied efficacy, and meets with the most constant and permanent success (though of course with many failures) in cases of rheumatism, neuralgia, dyspepsia, chorea, dysmenorrhœa, amenorrhœa, and other affections associated with general debility that for some cause refuse to yield to ordinary remedies.

Localized electrization, such as has been universally adopted by the European electricians, has indeed been essayed in a number of diseases, but is chiefly indicated in, and is now used by, all advanced students of nervous diseases, for the different forms of paralysis. On the other hand, *general electrization*, which is the method that we have introduced to the profession, differs from this as widely in its indications and effects as it does in the rationale of its performance.

It is not electricity in the abstract, but electrization in the concrete that cures diseases. The effects of electricity on the human body depend entirely on the manner in which it is generated and the method by which it is employed, and no observation in electro-therapeutics is worth anything that does not express distinctly whether the galvanic or Faradaic currents are used, and whether the electrization be localized, partial, or general.

RUPTURE OF THE HEART.

BEING REMARKS MADE AT A MEETING OF THE PATHOLOGICAL SOCIETY, OCTOBER 9, 1867.

By W. B. LEWIS, M.D.,

NEW YORK.

On the 9th of October, at the request of a member, I presented to the N. Y. Pathological Society the heart of a physician of this city who died in his sixtieth year, after an illness of about ten hours, of rupture consequent upon fatty degeneration of the heart.

On the Saturday previous the doctor was in his usual health. On Sunday morning he arose, but having a headache and feeling out of sorts, went back to bed. During the day, which was passed quietly, he took some light food, and at tea-time joined the family and seemed much better. About nine P.M., while writing some letters, he was seized with a severe pain in the stomach. It passed off in a few minutes, so that he wrote again, but it soon returned, and was then felt in the back also, between the shoulders. The agony became intense, and was not relieved, although fomentations and sinapisms were applied, and opium and chloroform were taken internally. He was sure he had stricture of the stomach, and to overcome this would rise from the bed and provoke vomiting by drinking warm water freely, and then lie down and strain like a woman in labor. Although he was fully conscious of the influence of the medicines taken, the pain continued without abatement until an early hour in the morning, when he slept for a few minutes while sitting in a warm bath. About half-past seven A.M. he arose and renewed his efforts to remove the difficulty by vomiting. To accomplish this he passed his fingers as far as possible into his throat, and strained frightfully. As soon as he was again upon the bed he said, "Something has given way; there will be a change soon." He died a few minutes after this, breathing most quietly to the last.

Several times since last January he had suffered in a similar manner, but less severely and for a shorter period, and on each occasion had gradually found relief.

The post-mortem examination was made early on Wednesday morning. The body was then very thoroughly chilled and stiffened by the ice with which it had been surrounded. The subcutaneous layer of adipose was more than an inch in thickness, and that beneath the peritoneum more than one-quarter of an inch. The lungs appeared normal. A quantity of blood-stained serum escaped from a wound in the pericardium, produced while removing the sternum. The abdominal organs, except a small portion of the liver, were hidden beneath a mass of fat. The great omentum was strangely loaded, being not less than an inch and a half thick at its junction with the transverse colon. The stomach was entirely normal, presenting no thickening or other change at any part of its walls, except that in the fundus there was a slight blackish stain upon the mucous membrane. It contained about an ounce of a thick, greenish fluid, such as is found during the later stages of digestion. The liver was engorged with blood, and evidently fatty; the mottling produced by intra-lobular congestion being quite marked. The gall-bladder was full of bile, a little thinner and lighter in color than usual; no concretion was found in it or its duct. Upon slitting up the pericardium an irregular laceration of the walls of the heart, three-fourths of an inch long, was at once noticed, situated about midway, from above downwards, and a little to the left of the inter-ventricular septum. The visceral pericardium, however, was torn only at two points, the larger of which would admit the end of a large-sized probe. Placing the finger upon this portion it could be easily depressed, showing that the walls were very thin and much softened beneath. The pericardium contained some loosely clotted, dark blood, not having the arterial hue, nor by any means forming a cast of the sac.

Upon opening the right ventricle it was found firmly contracted. No lesion of either valves or cavities was found upon this side. On the left side, in the sinuses of the semilunar valves, were whitish, slightly elevated spots of atheroma in an early stage. Near the apex of the ventricle, anteriorly and to the right, was an extensive *transverse* laceration, rather more than an inch in length, the columnæ appearing discolored and ragged upon its edges. The new cavity thus produced was evidently not made at one time, as it connected with at least two sinuses which could be traced upwards towards the base of the organ beneath the pericardium and fat. One of these opened into the right ventricle through one of the venæ thebesii, near the origin of the pulmonary artery, and upon the right surface of the septum. A peculiarity of this rent was that it was of the transverse variety, which numbers about one-fourth of the recorded cases, the majority being parallel with the fibres of the heart. There were two other partial ruptures, one to the left, and another below this fatal one; it seemed that either of these might in time have caused death. The tissue of the organ was of a duller shade than is normal, and remarkably friable, more so than the liver in this case.

A small portion clipped from the neighborhood of one of these partial ruptures was examined microscopically. Much the greater number of the fibres were granular, semi-opaque, and either devoid of, or but faintly showing their striæ; some had a column of more or less irregular fat globules occupying their centres; some, though few, were transparent, and presented the striæ clearly. Numerous free oil globules of various sizes were seen floating in the field. The granular particles were not resolved into globules by a power of five hundred diameters, although it was supposed that such was their real form.

Allow me to call attention to the location of the greatest and most constant pain in the *epigastrium*. This obscured the diagnosis, and has remained in a measure unexplained, to some at least, by the autopsy. I have recently learned of a similar case in which, after a few hours of great agony, also referred to the epigastrium, and thought to be due to biliary calculus, the patient died of rupture of the left ventricle of the heart.

LIGATION OF THE SUBCLAVIAN ARTERY FOR ANEURISM OF THE HUMERAL AND BONY TUMOR.

By E. P. BENNETT, M.D.,

DANBURY, CT.

Ligation of this artery is not so rare or so difficult as to excite any particular interest, but there were some circumstances attending this case which, perhaps, make it worth recording. The patient was a hatter, of good habits and constitution, about thirty years of age. Some two or three years ago he perceived a small tumor on the inner side of the humerus, near the axilla. It increased slowly in size until about the first of July, when he requested my opinion in regard to its nature and treatment. Upon examination I found a rough, sharp tumor, in shape like a cock's comb, about two inches long, and three-fourths of an inch wide. As it

produced but little inconvenience, I advised him to let it remain and watch its progress. He returned in about a week, and said that while engaged in moving, the tumor had suddenly increased in size, and was exceedingly painful. Upon examination I could with difficulty feel the bony projection, as it was covered and obscured by a large pulsating tumor the size of a large orange. There was a brachial aneurism situated near the axilla, the artery having probably ulcerated from the pressure of the bony projection. I immediately, with the aid of my son, Dr. W. C. Bennett, and Dr. A. C. Benedict, of Bethel, proceeded to tie the subclavian after its passage through the scaleni. The pulsation, which before was excessive, immediately ceased after tightening the ligature, and never returned; the tumor soon becoming soft and flaccid. The ligature came away on the twenty-fourth day, and he has done remarkably well. He has now returned to his ordinary labor, that of a hat-finisher, and is able to perform an ordinary day's labor; the temperature of the arm is natural, but no pulsation has yet returned in either of the arteries at the wrist. More than this, as yet no increase of the bony tumor has occurred. Sufficient time, however, has not yet elapsed to ascertain definitely what effect the ligation of the artery will have upon its growth. If it continues to grow, I shall cut down upon and remove it with a longitudinal portion of the shaft of the bone from which it proceeds, which will, in all probability, entirely eradicate the difficulty. I removed a similar tumor from the arm of a gentleman now living in Middletown, N. Y., with gouge and chisel, taking away about half of the bone, with entire success.

Reports of Hospitals.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA.

MEDICAL CLINIC OF PROF. CARSON.

Philadelphia, Oct. 16, 1867.

FLATULENCY.—The patient, a married female, about thirty years of age, has been subject to flatulency for a period of fifteen years. The character of the complaint in the patient is the emission of wind, or of certain gases from the stomach, sufficiently loud to drown the lecturer's voice, these emissions occurring about every half minute. She has no feeling of discomfort, although she does not feel so well in the evening as in the afternoon. Has no difficulty in breathing, does not suffer from headache; sometimes feels an oppression about the heart; no palpitation in going up stairs; pulse strong and regular, but not rapid—beats eighteen to the quarter; rhythm of the heart perfect; the impulse is very moderate, the two sounds are perfectly perceptible; nothing is the matter then with her heart. There is a perceptible gurgling from her alimentary canal extending all the way up into her thorax. The sounds of respiration are thus rendered indistinct. She became pregnant in the spring, but from derangement of the alimentary canal was unable to go through the full term and miscarried. There is no perturbation of the nervous system.

From a peculiar condition of the alimentary canal in nervous cases, this secretion of air generally comes on all at once, and it is said to be connected with disturbance of the ganglionic system. In some cases irritation about the centre of the spine will induce this secretion of wind, if it is secretion, which the lecturer doubts, because the canal does not secrete gas, the presence of which is much more likely to be due to some decomposition. The manner in which the gas is formed, however, is a disputed point. There is no perceptible odor from this emission, though it may nevertheless be hydrogen gas, which is sometimes generated in the alimentary canal; still, it may be some other matter.

This case appears to be a pure specimen of reflex action, producing a generation of gas in the alimentary canal, come from whatever cause it may. There is a distension of the stomach, and the diaphragm so presses upon it as to bring up the gas by eructation; so that it may be looked upon to a certain extent as nervous. The lecturer said that he had always found it advisable under this condition of things, when there was a tendency to a secretion of gas, if it be secreted, to use the terebinthinates, for example spirits of turpentine, and at the same time to keep the bowels regular and in a soluble condition, for which he found nothing better than a warm cathartic; sometimes asafœtida is of great assistance—it is a nervine. The patient was ordered, upon going to bed, a couple of pills, each containing a grain of rhubarb, a grain of aloes, two grains of powdered asafœtida, a grain of soap, and half a drop of some essential oil; and to take three times during the day five drops of spirits of turpentine in emulsion with gum and sugar.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, OCTOBER 8, 1867.

DR. A. C. POST, CHAIRMAN *pro tem.*

ŒDEMA OF THROAT AND TONSILLAR CONCRETION.

DR. SAYRE exhibited a specimen, and gave the history of it as follows: On Sunday a week ago I was called in great haste to a lady who was supposed to be suffocating with diphtheria. I found the patient, æt. 60, sitting up in bed with all the symptoms of impending suffocation—her expression was anxious, and her respiratory efforts were painfully difficult. Upon examining her throat no evidences of diphtheritic deposit could be discovered, but there was to be seen an œdematous condition of the tonsils, the epiglottis, and of the fossa beside the epiglottis. Fearing, from the urgency of her symptoms, that strangulation might ensue from any delay, I immediately slit open the œdematous membrane with a bistoury, and, in doing so, felt the blade strike upon a roughened hard substance. My first impression was that this material was a piece of oyster-shell. An abundant discharge of thick ropy mucus followed the incision, and there was immediate relief of all the urgent symptoms. By fishing in the throat with a forceps, the foreign body could be distinctly felt, but not having a curve to the instrument to enable a grasp to be taken of it, it was removed by means of a bent probe. On examination it proves to be a concretion evidently formed in one of the follicles of the tonsil. It lay upon the left side of the epiglottis in the fossa between the columns of the tonsil. There was no tonsillitis at the time, but whether there was any before I am not able to say. In answer to some questions from the members he stated that severe dyspnœa had existed for eight hours previous to his having seen her, and that she had been sent down from Yorkville by her physician, who had supposed her suffering from diphtheria. The extent of the incision could not be stated, as, for obvious reasons, it was made in a great hurry. The œdema was mostly upon the left side of the throat.

DR. ROGERS, who kindly examined the concretion,

makes the following report:—The specimen is one whose exterior appearance is very well described by Dr. Gross in his Elements of Pathological Anatomy. When speaking of earthy concretions in the tonsils, he says, "they usually have a white, greyish, or light-brownish color, a spherical figure, and a finely tuberculated surface." I presume these different shades of color result from the different proportions of animal substances composing the concretions. This one is quite dark on account of the large amount of animal substance it contains. It is composed of carbonate of lime mostly, and dissolves in the acids with effervescence, leaving an abundant residuum of dark-brown animal matter, which, upon examination by the microscope, is found to be composed of a mass of ill-defined cells or corpuscles, or both, intermingled with a few pavement epithelial scales. I have little doubt that this animal debris is composed of follicular epithelial scales, altered pus and mucous corpuscles, as well as an occasional pavement scale, from the adjacent mucous membrane. The stone is undoubtedly a concretion in one of the follicles of the tonsils, the result of old folliculitis.

Dr. Jacobi did not understand the connection which existed between the œdema and the presence of the foreign body. He had met with some cases, and read of many more, in which foreign bodies of the same description in the throat produced distressing symptoms, but in none of these was there any œdema of the glottis.

CARIES OF HEAD OF FEMUR WITH EXSECTION.

Dr. Sayre presented a second specimen, consisting of caries of the head of the femur with some portions of the acetabulum, which he removed by excision that day from a child six years of age. Eighteen months ago, having been previously in good health and of healthy parents, the patient fell from a swing some seven or eight feet, striking upon the feet. This accident was followed almost immediately by a sharp inflammation of the hip-joint, resulting at first in considerable lameness. At the end of three or four months afterwards the patient was able to walk about, but never entirely recovered the use of the limb. The child last fall was brought to Dr. Sayre's office, but he being absent from the city the case was treated by other surgeons until he returned. The day but one before he operated. There was such extreme abduction of the thigh of one side that the knee lay behind the lower third of the femur of the opposite side. There was an opening near the posterior spinous process of the ilium, and another just behind and below the trochanter major. On careful examination under chloroform by pressure and rotation no crepitus could be detected. If the evidences of the existence of this condition were the only ones that could settle the question of destructive disease in the joint, the operation would not have been performed; but notwithstanding the absence of this important sign Dr. Sayre concluded from the position of the limb that there was a destruction of the head of the bone.

The incision was, as usual, slightly curved, and the head of the femur was sawn off just below the trochanter. On removing the diseased mass, the head of the femur was entirely gone and its place occupied by a pulpy, elastic, and pinkish looking substance resembling India-rubber in consistence. The child was dressed up in the ordinary way by Bonnet's wire breeches. Although the bone was soft at the point of section the periosteum was intact below, and Dr. Sayre thought that the chances for recovery were good. He recognized the softened condition at the time, but it being the opinion of the gentlemen present that a section at the point would be low enough, he acquiesced and performed the operation accordingly. The treatment by elastic extension had not been tried by the surgeons having previous charge of the case, otherwise the operation in his opinion would doubtless have been uncalled for.

In conclusion, he stated that it had now been nearly two years since he had presented any specimen of exsection of the femur, since which time he had removed three with a good result, and one where death ensued. This made in all twenty-three cases, with only six deaths.

RUPTURE OF THE HEART.

Dr. Lewis presented a specimen of rupture of heart (*vide* page 412).

Dr. Hamilton stated that in 1860 he made an autopsy of a gentleman who died of a rupture of the left ventricle. The patient was sixty years of age, and of a robust constitution. He saw him twenty-four hours before his dissolution, when he was suffering from irregular and feeble action of the heart, and with a pain which he located chiefly in the epigastrium and somewhat upon the left side. The pain was supposed to be due to some disturbance of the stomach of which the action of the heart was merely sympathetic, more especially as he had been accustomed to such attacks previously; in fact, he had suffered from a similar one on the very day Dr. Hamilton first saw him, but not quite so severe as the one referred to. From this last attack he never recovered. A post-mortem examination was made, and, as far as he could remember, the heart seemed to have undergone fatty degeneration. There was a fissure near the apex of the left ventricle. The walls of the heart were very much thinned. The rent was a very small one, and but three ounces of blood were found in the pericardium.

Dr. Eliot, who had attended the medical gentleman whose case was reported by Dr. Lewis, stated that the deceased had repeatedly suffered from similar attacks of pain, which he had been accustomed to refer to stricture of the stomach, and when warned of their appearance would take some blue mass and be relieved. He was also in the habit of inducing emesis by thrusting his finger into his throat, with the idea thereby of relaxing the stricture. So much had he practised this manœuvre that at times he would almost insert his whole hand into his throat. He did not commence to ail until Sunday, when he was compelled to stay in bed until evening, and then arose and wrote a couple of letters. Shortly after this he was taken with the pain, which was so severe that he was forced to brace himself with his back against the door for relief, which, however, did not come, and he then went upstairs to bed. The remaining portion of the history was already known.

POISONING BY LAUDANUM.

Dr. Finnell exhibited the uterus and appendages of a young lady who had been poisoned by an overdose of laudanum. She had eaten a very hearty dinner in the evening about six, and two hours after, while suffering from some pain, it is not known where, she took some laudanum from a bottle which had been standing for a long time without a cork. The quantity taken was not known, neither was the strength of the tincture ascertained. She retired about ten o'clock in a stupid condition, and in the middle of the night her aunt, who was sleeping with her, became alarmed at her heavy snoring, and made some ineffectual efforts to arouse her. The alarm was given, but all endeavors to resuscitate her

were unavailing, and she died at five o'clock the following morning.

The autopsy was made twelve hours after death. The stomach contained part of the meal taken the evening before, and there was a strong odor of laudanum perceptible when the organ was opened. Although the deceased menstruated a week before her death no recent corpus luteum was discovered. The uterus was intensely congested on its internal surface, and the os and cervix were plugged with a thick mucus.

EXTENSIVE EXTRAVASATION OF URINE.

DR. BUCK presented a specimen of a bladder and urethra taken from a man thirty-seven years of age, who was admitted on the afternoon of the Thursday before into St. Luke's Hospital. He was represented to be a hard drinker, and was in a condition verging on collapse from extensive extravasation of urine. The antecedents of his case were very imperfectly related. It was represented that a swelling, to be presently described, had existed for three days. The scrotum was distended almost to the size of a fœtal head, was shining and tense. The penis was swollen and œdematous, not tense, and the pubes was distended, and the flanks above and on a line with Poupart's ligament were very considerably swollen and elevated. This condition was particularly marked on the right side. The surfaces of these swellings were mottled and had a hard appearance, and when pressure was made the patient made decided complaints of pain. Fluctuation could be felt in the right iliac region. The perineum was also distended and tense.

The first step in the performance of an operation for the relief of the patient was the making of a free incision along the raphe of the scrotum for two-thirds of its distance, splitting it to the depth of two inches, and carrying the incision back along perhaps half the extent of the perineum. This passed through infiltrated tissues of a greyish aspect, and the incision far back towards the perineum arrived in a cavity, which was found to spread extensively and give escape to a very fœtid discharge. An incision was also made in the right iliac region over the most prominent portion of the swelling, and from that a very considerable discharge of bloody, watery fluid took place. The tissues exposed by this incision were dark, and evidently in a condition verging on gangrene.

The patient hiccoughed occasionally; his countenance was of an ashy hue, and his whole aspect, as well as condition of pulse, was that of impending collapse. He was also represented to have vomited previously.

No attempt was made to relieve the bladder at that time; in fact, it was thought best not for the present to proceed any further. Every means was used to sustain his strength, and it was hardly suspected that he could survive the night. But next forenoon he was still alive, and reaction to a certain extent had taken place; the hands were of the natural warmth, and the pulse was a shade better. The scrotum had very considerably collapsed from the drainage, which was also the case with the flanks, particularly the right.

At this time it was thought proper to make an effort to introduce a catheter. The swollen condition of the prepuce, however, prevented the meatus from being brought into view. After repeated attempts to strike the meatus with the catheter without success, the prepuce was laid open throughout its whole dorsal portion. It was then discovered that a tight stricture existed about three inches from the meatus. A No. 2 bougie could be tightly engaged in the constricting band. To get through it the following expedient was resorted to: A No. 1 bougie was engaged in the stricture, and the free end of the instrument cut off. The penis being held straight and a little stretched, the canula of a small trocar was passed over the bougie until it rested upon the anterior surface of the stricture. The bougie was next withdrawn and in its place an appropriate trocar was placed, which was thrust against and into the stricture. This permitted the bougie to be passed through the stricture, but not far into the urethra. An attempt was then made to introduce Holt's instrument, when it was found that by a little moderate pressure it could be advanced pretty well into the stricture, at least sufficiently to arrive at the remotest part of its dilating portion. The dilator was then passed and thrust home, and upon withdrawing it it was found that a Holt's instrument closed could be passed sufficiently far to be engaged into the neck of the bladder. A larger sized instrument was next passed home, resulting in the further rupture of the stricture. This permitted the entrance of a tapering No. 10 bougie into the bladder, and afterwards of a good-sized catheter, when eight or ten ounces of urine were drawn off. The urine being clear and free from any admixture, it seemed fair to infer that the bladder was not suffering from any catarrh or other form of inflammation.

The catheter was left in, with directions to draw off the water at stated intervals, and the general treatment was continued. He was admitted on Thursday, and survived until five o'clock Sunday afternoon.

The specimen showed that the interior of the bladder was free from disease, except the thickening of its coats, which condition would naturally coexist with a stricture taxing the muscular power of the viscus. The anterior limit of the membranous portion was the situation of the opening through which the extravasation took place. This was large enough to admit of the introduction of a No. 6 or 7 catheter. The external incision had communicated with the cavity immediately external to this. The laceration of the urethra occupied about the space of an inch, and extended into and exposed the tissue external to the urethra. There was no appearance of any stricture posterior to this.

The question in connection with this rupture suggested itself, whether this extravasation had been preceded by an abscess communicating with or opening into the urethra, of limited dimensions, and whether the rupture of the walls took place when the extensive extravasation occurred. In reference to the probability of this condition of things, he cited an instance of similar cases that were occasionally admitted to hospitals. Patients with old and tight strictures will occasionally call attention to a lump in the crotch. On examination, a deep, hard, circumscribed swelling will be found situated a little to one side of the median line embracing the urethra. The skin will be movable over it, and perhaps not, and perhaps the prominence cannot be recognized. On handling the parts, however, a firm hard tumor is discovered. An exploration of the urethra shows a stricture at the level of this tumor. That swelling is evidently an abscess. Fluctuation cannot be felt in it at first, but its progress is this: The constant action of the *vis a tergo* of the urine crowds the excretion into this abscess, at first small, and keeps up a constant irritation there tending to enlarge it. As it enlarges it produces adhesions, until the integument becomes involved and an external opening is established. But in the progress of this abscess towards the surface, an ulcerative process may be going on internally, and may even get the start of the pointing externally and establish a communication direct with the neighboring cellular tissue, which will in some instances extend so that it may even infiltrate the walls of the abdomen.

In the present instance it was Dr. Buck's opinion that the latter condition obtained. In conclusion, he recommended that such tumors, when found in connection with strictures, should immediately be freely incised in anticipation of trouble that was otherwise sure to come.

POST-MORTEM LESIONS IN FOUNDLINGS.

Dr. Lewis Smith exhibited specimens which illustrated some of the post-mortem lesions that were to be met with in foundlings. He remarked that a comparatively small proportion of foundlings live beyond six or eight months. They come in charge of the city at the age of about a week, and are placed in an institution, and there, with all the possible care that can be given them, they soon begin to waste away, diarrhœa soon occurring, and continuing until the close of life. In many of these cases there is a dry cough, while in others, during the last day or two, symptoms of hydrocephalic disease manifest themselves. In that latter condition the infant becomes, of course, stupid, and passes into a state of collapse, the cause evidently being referrible to inanition.

He presented the brains of two infants who had died under these circumstances; and the large and small intestines of two others.

In connection with the general post-mortem appearances of these cases, he remarked that usually there were evidences of intestinal inflammation, in the shape of injection and thickening of the mucous membrane of the colon. Sometimes this amounted to mere arborescence, and sometimes it was a matter of doubt whether it was simple congestion or not.

In the minority of cases there were no evidences of intestinal inflammation, the mucous membrane being pale, and the follicles and Peyer's patches being somewhat raised. The child then dies of a non-inflammatory diarrhœa. In the majority of cases there are signs of ulceration of the solitary follicles.

The condition of the lung was one of considerable interest, and corresponded with that described by writers as pneumonia induced by inanition—an advanced stage of hypostatic congestion caused by mere feebleness of the circulation. He remarked that for some time past he had given considerable attention to this state of the lung, and had come to the conclusion that in many instances actual pneumonia was caused by the presence of this accumulated blood acting as an irritant.

The brains of those who died with hydrocephalic symptoms were usually congested at post-mortem examination.

In the lungs exhibited there was at one spot well-marked gangrene. This state of things the speaker had repeatedly noticed before, and was inclined to believe that it was the result of general inanition, which was invited to that locality by the extreme feebleness of the circulation through a hypostatically congested part. There was no fœtor of the breath noticed in this case.

Dr. Jacobi could not understand why gangrene should be so localized, and yet dependent upon a general cause, and expressed the opinion that in all such cases some tangible mechanical obstruction must exist to explain it.

Dr. Bibbins believed that the great mortality of foundlings was mainly due to the insufficient supply of fresh air to the wards and rooms which they occupied.

In answer to a question, Dr. Smith remarked that the percentage of foundlings with gangrene of the lungs was about one per cent.

The Society then adjourned.

EAST RIVER MEDICAL ASSOCIATION.

Stated Meeting, October 1, 1867.

Dr. V. Morse, President, in the Chair.

THE ENDOSCOPE AS AN AID IN THE DIAGNOSIS AND TREATMENT OF GRANULAR URETHRITIS AND STRICTURE.

Dr. Stein having read the report of the section on diseases of the urinary organs, made a few remarks explanatory of the endoscope, which he exhibited. He alluded to the fact that gonorrhœa, or acute urethritis, in passing to the chronic stage, extends from the anterior to the deeper portions of the urethra, usually localizing itself at the bulbo-membranous region. The symptoms which indicate this period of the disease are well defined and always recognized; but the exact pathological condition of the urethral mucous membrane was the province of the endoscope to reveal, for by its aid we are enabled to explore the urethral canal, and have presented in an unmistakable manner the true lesions of this affection.

As the tube of the instrument approaches the seat of disease, we observe an abnormal redness, which gradually increases, and becomes most marked at the bulbo-membranous region; at this point its surface appears unequal; these inequalities increase in size and number, and finally form deep-red rounded eminences or granulations, which impressively resemble the granulations of granular conjunctivitis. This condition being accepted as constituting the affection familiarly known as *gleet*, is now more properly called *granular urethritis*. If these granulations are neglected they will sooner or later inevitably lead to the formation of organic stricture; but if timely discovered, direct topical applications through the tube of the endoscope of sol. argenti nitratis (xx. to xxx. grs. to aq. ʒ i.) will remove them, and restore a healthy condition to the mucous membrane.

In impassable organic stricture the endoscope enables us accurately to appreciate its anterior configuration and the exact position of its orifice, so that in case of retention of urine we can afford relief by introducing a small catheter, and obviate, perhaps, the necessity of perineal section or puncture of the bladder. Furthermore, in the operation of internal urethrotomy we have the eye as a guide, and can better limit our incision to the indurated and strictured part, than by any other means.

The field of labor of the endoscope is not confined to the urethra alone; Desormeaux has lucidly demonstrated its utility in the examinations and treatment of the diseases of the mucous membrane of the bladder, cavity of the neck and body of the uterus, ovarian cysts, upper part of rectum, and also in discovering the presence of foreign bodies in deep wounds.

The want of interest manifested in the endoscope, considering that its value is relatively equal to the speculum, laryngoscope, and ophthalmoscope, by many of the profession, is not a little surprising.

Dr. O. J. Ward coincided with Dr. Stein's views, but thought that the value of the endoscope would be still farther enhanced if some means might be devised to keep the transparent orifice of the tube from being obscured by the blood which followed its introduction. He had seen it introduced in two instances, and at each occasion this constituted quite an annoyance.

Dr. Buttles had for some time been in the habit of using a hollow glass tube, whose walls were strong enough to obviate any danger from fracture, into which he directed the light reflected from the mirror in ordinary use by aural surgeons. In this way he obtained a pretty accurate idea of the condition of the urethra, and made his topical applications accordingly.

Dr. Stein had no doubt but that this plan answered well enough in certain cases, particularly where the lesion occupied the ordinary site; still he thought that the endoscope was better adapted to a wider range of investigation.

In reply to a question, he thought that the addition of a few grains of camphor to the oil increased the brilliancy and whiteness of the light. Dr. Bumstead's formula was pulv. gum camphor, grs. xv.; kerosene oil, ℥i.; solv. Dr. Andrews in the *Chicago Med. Examiner* extols the magnesium light. He would also state that Dr. Weir of this city had made a very ingenious modification of Desormeaux's instrument, which might be seen at Mr. Tiemann's establishment in this city.

The meeting then adjourned.

MEDICAL SOCIETY OF THE EASTERN DISTRICT OF BROOKLYN.

Stated Meeting, September 19, 1867.

DIABETES MELLITUS.

Dr. Wieber read a paper on Diabetes Mellitus, of which the following is an abstract:—

He first referred to a case of diabetes which, at the time of writing, had been twenty months under his observation. The patient, a girl aged seven years, had complained for several weeks before medical advice was summoned; at this period, January, 1866, the case presented all the symptoms of diabetes. The urine, which was discharged in large quantities, bore a specific gravity of 1040, and when examined by different tests proved to contain a large amount of grape sugar. The patient was put upon animal food, and the only medicine prescribed was "artificial Vichy water," of which from one to two pints were taken *per diem*. Under this treatment the patient gradually improved, the thirst became less urgent, and the sugar in the urine diminished. At intervals, amylaceous food was allowed, and wine given in small quantities. After six months of this treatment there was scarcely a trace of sugar in the urine, the patient had always a good appetite, and had gained strength. A few months after, this sugar again made its appearance in the urine, but the patient's sufferings were slight. She drank less than before, and the discharge of urine diminished. At present, having been twenty months under treatment, the girl is attending school, and considered well by her parents; but the urine, which has a specific gravity of 1020, contains sugar, which shows that the disease is still going on. During the whole time of treatment no medicine other than the Vichy-water has been given the patient.

Dr. Wieber presented to the Society specimens of chemically pure grape sugar made by himself from the urine of his patient; he also showed, by different tests, the sugar in fresh urine from his patient, of which the following are the simplest and best. First—Take about fifteen or twenty drops of urine diluted with four or five cubic centimetres of water, and about one-half C. C. liq. potassa caustic (or liq. soda caustic), and then, by drops, a very dilute solution sulphate of copper; should there be sugar in the urine the precipitate by agitation will dissolve, forming a clear blue liquid; without agitation the blue liquid has to be heated near to the boiling point, at which a red or yellow precipitate of suboxide of copper will appear. Caution is here necessary lest too much of the copper solution be used. Another portion of urine may be treated in the same way, with the exception of heating it; in the course of twenty-four hours' precipitation will take place if sugar is present.

This second test is important, and never to be omitted, as other abnormal ingredients of the urine will cause a reduction of copper when subjected to heat in this way.—(Trommer's test.)

Second—Take a small quantity of urine in a narrow test tube, add a solution of caustic potassa, and heat the upper part of the liquid; when, if sugar be present, it will become of a yellowish brown color.—(Moore.)

Third—Take equal parts of urine and solution carbonate soda (made of one part carb. soda to three of water), add a small quantity of nitrate of bismuth; apply heat for some minutes, after which the bismuth turns to a gray or black color, according to the quantity of sugar present.—(Boettches.)

Another sure method of testing diabetic urine is by the decomposition of sugar into alcohol and carbonic acid, by adding yeast to the urine.

Referring to different theories of diabetes mellitus, Dr. Wieber quoted from Prof. T. Vogel—Diseases in Urinary Organs. However the organization of sugar may be explained, to cause mellituria, sugar must be accumulated in the blood and is dissolved in the serum, which in patients suffering from diabetes mellitus has a higher specific gravity (1033 instead of 1029).

This concentrated blood serum is absorbing, according to the law of endosmosis, the water from the liquids of the parenchyma as well as from water taken with the food and drink. In consequence of this the blood-vessels are overcharged; a plethora takes place, which causes a higher degree of pressure in the vascular system, especially in the kidneys, resulting in polyuria. By this theory the thirst, dry skin, and other symptoms of diabetes mellitus are easily explained.

The duration of diabetes mellitus is very variable. Prof. Griesinger, of Berlin, recorded one hundred cases, ranging as follows:—

Less than a quarter of a year, 1; quarter to one-half, 2; one-half to one, 13; one to two, 39; two to three, 20; three to four, 7; four to five, 2; five to six, 1; six to seven, 2; seven to eight, 1.

Twelve cases were uncertain. Griesinger found that from two hundred and twenty-five cases, seventy-six per cent. were males, and twenty-four per cent. females. Considering the age, there were under

Ten years, 6 cases; ten to twenty, 36; twenty to thirty, 46; thirty to forty, 60; forty to fifty, 36; fifty to sixty, 14; sixty to seventy, 7; seventy to eighty, 1.

According to Griesinger's collection of post-mortem examinations of sixty-four cases, there were forty-three per cent. complicated with tuberculosis pulmonalis, and thirty-two cases were kidney diseases, viz.—hyperæmia, 5; enlargement, 7; abscess, 3; Bright's disease, 17.

On motion, the Society then adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Nov. 3, 1867.

Dr. Edmund R. Peaslee, President, in the Chair.

SUMMARY OF THE PRESIDENT'S ADDRESS.

Dr. Peaslee delivered the inaugural address, the subject of which was "The Aims and Qualifications which Conduce to Render Man an Ornament to the Medical Profession." After referring to the veneration paid to the science of medicine by the ancients, he invited attention to the qualities that were essential to make a physician an aid to his fellow mortal and an ornament to the profession. The first requisite was a sound, thorough education before entering into practice. He then instanced some of the evil results which followed the efforts of young

men who practised medicine without first gaining a knowledge of the studies which should precede that course. A study of anatomy should precede physiology, and that of both, pathology. He next alluded to the brief time allowed in some colleges for the graduating of students, and characterized the system as one that did great injustice to the students and the public. He also showed the importance that a physician in practice should keep himself fully informed, by reading, of the new principles developed in medicine, and took the ground that a physician should not allow any other occupation to interfere with his profession. He recited numerous instances to prove that many physicians, whose names are eminent in history, and whose practice was exceedingly laborious, found ample time to read and write medical works. A physician could not expect to gain eminence at once, and young men need not despair of achieving fame. It took Harvey thirty-six years to perfect his system of the "Circulation of the Blood." Neither did advanced age disqualify men from engaging in active business pursuits, and it would not do for a physician to rely wholly upon his experience. There was always something to learn; and practice did not necessarily give experience. Another requisite to the success of the physician was piety. The speaker closed his address with an appeal to his hearers to observe those qualities which tend to make the profession useful and eminent.

Dr. Roosa then read a paper entitled, "Remarks on the Diagnosis and Treatment of Diseases of the Ear."

Dr. Griscom followed with a description of a new form of Family Record.

The Society then adjourned.

Progress of Medical Science.

The Treatment of Contracted Muscles and Tendons.—The treatment of contracted muscles and tendons, as advised by Dr. H. G. Davis, of this city, in his work on *Conservative Surgery*, is based upon the good effects of a state of constant tension. The author maintains that whenever any circumstance shortens the relative distance between the points of origin and insertion of any muscle or tendon, there is an absence of the natural stimulus to the normal nourishment of the parts; that, in other words, no more of the nutritive element is effused than is barely requisite to maintain such tissues in their shortened condition. If, under these circumstances, extension is employed by the elastic method, the contracted tissues are kept constantly upon the stretch, and are gradually elongated to their normal dimensions. As a consequence of this continuous tension of the fibres, the supply of nourishment is proportionately increased, so that eventually, by the constant supply of new material, the parts actually grow to their natural length and original strength. His observations with reference to this point have, he assures us, been amply and satisfactorily proved as the result of fifteen years of experience.

The advantage of elastic extension over other methods consists in the fact that it is constantly kept up, and that, as the muscles or tendons give way to the force exerted upon them, there is always enough power of extension in reserve to keep up the action and follow up the good effects. This continuous tension stimulates the deposit of new material, so that the growth of such shortened tissues is more rapid than under ordinary circumstances. As extension is ordinarily kept up by inelastic bands, the force is constantly liable to be reduced by the relaxations of the appliances, which must, in a longer or shorter time, yield to the stretching to which they are subjected. This principle can be satisfactorily applied to all cases in which it is necessary to overcome undue contraction of the soft parts from any cause save actual organic interruption of nerve power; such, for instance, as in deformities attendant upon contractions after inflammations of the joints, upon the different varieties of talipes, upon the deformities after fractures and old dislocations, and even upon the retraction of the integuments after burns. In the latter case the strain is put upon the surrounding skin by means of adhesive plaster in opposite directions to the contracting forces in the ciatrices. The general plan of treatment has to be modified in accordance with the special indications that may be present in each case, constantly calling the ingenuity of the surgeon into play. He does not consider division of the tendons as at all necessary for the accomplishment of permanent elongation of contracted parts, and affirms that continuous elastic extension, intelligently employed, is all-sufficient to overcome the most obstinate contraction.

In many cases where muscles are firmly contracted, and antagonistic ones, by constant stretching, by derangement of nerve force and deprivation of proper nourishment, are paralyzed, he assists nature by supplying by means of india-rubber webbing an artificial muscle on the paralyzed side. By this means the contracted muscle is not only elongated, but its antagonist is proportionately shortened, and in both instances the power of muscular co-ordination is regulated by an equal distribution of nerve power.

Again, in order to exercise more power upon the contracted muscles, he employs pressure upon their bellies; at the same time makes use of the elastic extension besides. This is accomplished by employing two sets of adhesive plasters, so arranged fan-fashion, one strip overlapping the other, that they will cross each other over the belly of the muscle. To the smaller extremities of each one of these sets is sewn a piece of elastic webbing to which the extending force is attached. If it is desired, for instance, to make extension by this means upon the extensors of the thigh, strips of plaster are applied from below upwards diagonally across the front of the thigh, first upon one side and then upon the other, the sets crossing each other at acute angles in the median line of the limb. A firm roller is applied over the whole to keep the plasters in position, while, to the ends of the strips as they lap upon each other, on both sides of the knee strong webbing is sewn for the purpose of connecting with the elastic extension below. Extension being applied, the extensor muscles are not only put upon the stretch, but the diagonal position to the two sets of plasters by virtue of the direction of the strain, compresses the bellies of these muscles besides. This plan of treating muscles is not only applicable to cases of joint-disease and the like, but may be advantageously employed in cases of fracture in which the powerful action of a certain set of muscles obstinately tends to keep up a constant separation of the two fragments. In attaching the elastic webbing to the soft parts the ordinary adhesive plaster carefully and smoothly applied is always used, and is in turn maintained in its position by nicely adjusted bandages.

Next to a fair share of mechanical ingenuity in the use of this method of extension, success is only gained by the exercise of much patience and firmness on the part of the attendant, so that a constant stretching of the parts day and night be kept up for weeks. Intermissions in such a course, if allowed to occur either by neglect, design, or discouragement, are attended with the loss of much more ground than at first would be expected, owing to opportunities thus granted to the contract-

ed tissues to recover in some degree the strength of habit.

As an evidence of the good effects of this method of extension, Dr. Davis asserts its power to relieve the pain which is sometimes such a distressing accompaniment to some forms of muscular contractions. He believes that the contraction of the muscles around diseased joints is first produced by an effort of the will to hold the parts motionless and in as comfortable a position as possible, and that the muscles getting into the habit of contraction, the exercise of the will is no longer necessary to keep up the contraction.

A Fracture of the Cranium, with penetration of a bony spiculum into the brain and loss of brain substance, is recorded in the *Gaz. des Hôp.*, the remarkable feature of which was recovery within six weeks.

The Arrest of Hæmorrhage by Acupressure (if we may judge by the tenor of several articles in the *Medical Times and Gazette*, the *Lancet*, and in special treatises) is steadily growing in favor. It is claimed for this method that it is not only an efficient hæmostatic, but that it accelerates the healing of wounds, and that "union by the first intention" has been repeatedly effected in stumps of the thigh without a *drop of pus!*

The experience of our own surgeons is rather adverse to this mode of treatment, it having been found in several instances that a suppurating tract had been established by the needle.

The Styptic Collodium composed of tannin, alcohol, ether, and gun cotton, is highly extolled by Dr. B. W. Richardson, in the *Med. Times and Gazette*, as favoring "union by the first intention."

The Extirpation of Nævi by Enucleation.—An article "on the enucleation of nævus" appears in the *Brit. Med. Journal*. This advance in treatment is the result of Mr. Paget's investigations. He demonstrated the existence of a distinct sac in these cases, and upon this fact is based the above-mentioned operative procedure.

Shampooing in Sprains.—M. Beringer Ferand (*Bull. de Thér.*) advocates shampooing in the case of sprains. He advises the attendant to begin with gentle passes and movements, to be gradually increased in force. Cold lotions and rest should follow. The manipulations should always be towards the body.

Applications for Carbuncles after Incisions and Indolent Ulcers.—A solution of permanganate of potash (℥ ss.–℥ j.) is strongly advised as a dressing after the incision of carbuncles, and as application to ulcers. —Dr. Leavitt, *Am. Journ. Med. Sciences.*

Another writer (Dr. D. A. Morse, *Med. and Surg. Reporter*) prefers the claims of the following application in indolent ulcers, where the tissues are dark and indurated. ℞.—Plumbi subacet., 7 parts; pulv. opii, 1 part; hydrarg. submur., 2 parts. He claims that it relieves pain, induces a healthy appearance, etc.

Period of the Growth of Man.—Prof. B. A. Gould, from statistics derived from the register of two and a half millions of men in the United States Army, has brought out the fact that men attain their maximum stature much later than is generally supposed. This takes places commonly at 29 or 30 years of age; but there are frequent instances of growth until 35, not very noticeable—a yearly gain of a tenth of an inch, perhaps—still a growth. After 35, the stature subsides in similar proportions, partly perhaps from the condensation of the cartilages, partly because of the change occurring in the angle of the hip bone. The age for maximum stature comes earliest to the tallest men, as if it were the necessity of unusual development. Foreigners were shorter than men of native birth. The height of men seemed to depend on the place of enlistment. A Massachusetts man enlisting in Iowa was an inch taller than if he had stayed at home. As we go west, men grow taller. One man measured more than 6 feet 10 inches. Out of 1,000,000, there were 5,000 who measured more than 6 feet 4 inches; but men of such stature do not wear well. In Maine, men reached their greatest height at 27; in New Hampshire, at 35; in Massachusetts, at 29; in New Jersey, at 31. The tallest men, of 69 inches, come from Iowa. Maine, Vermont, Ohio, Indiana, Minnesota, and Missouri, give us men a little over 68; and the average of all shows the Americans to be "a very tall people."

Magnetism not Resident upon the Surfaces of Bodies.—In a discussion on this subject, before the British Association, Sir William Thompson took exception to the remark that magnetism, like electricity, distributes itself upon the surface of bodies. The same statement had been made by authors of repute; but it only added proof to the fact that in many popular books there were statements not merely false in theory, but false as being in direct opposition to facts published many years ago. Harlow, in experimenting with bars of iron, found, long ago, that the magnetic influence was not discoverable. His experiments were not carefully made, yet he rashly stepped to the conclusion that magnetism resides at the surface; and, although it was soon proved incorrect by a celebrated mathematician, this statement has been the fruitful parent of many fallacies.

The most Frequent Seat of Urethral Stricture. —M. H. Follett (*Archives Générales de Médicine*, April, 1867; *Gazette Hebdom.* April 12, 1867) believes that organic strictures of the bulbo-membranous region, though pronounced to be frequent, are rare. He publishes six cases of organic stricture, of which one alone occupied the bulbo-membranous region, while the remainder occupied the spongy part.

The Treatment of Hydrocele of the Cord.—M. de Luci (*Gaz. des Hôp.*) reports a case of encysted hydrocele of the cord cured by alcoholic injections.

The Radical Cure of Varicocele.—Maisonneuve (*Edinburgh Med. Jour.*) recommends coagulating injections of the perchloride of iron for the radical cure of varicocele.

A Simple Remedy for Polypi of the Nares.—Dr. T. Bryant (*London Lancet*) treats mucous polypi of the nares with tannin used as a snuff.

Successful Closure of an Artificial Anus.—Dr. J. B. Graves (*Med. and Surg. Reporter*) furnishes a unique history of a case of strangulated hernia. Operation was performed, and followed by an artificial anus. In due time this was closed by Dupuytren's method. Twelve years after, the patient reports herself in perfect health; she can feel the transit of fæcal matter along the gut at the point where the artificial anus was, and can even assist its passage by manipulation.

A Rare Result of Catheterism.—M. Foucher (*Hôp. St. Louis, Gazette des Hôp.*) publishes a case where catheterism was followed by orchitis, suppuration and elimination of the tissues of the testicle, peritonitis, and death. The points of interest are: (1) An example of suppurative orchitis with elimination of the seminiferous substance. (2) The transmission of inflammation from the testicle and epididymis to the cord, then to a hernial sac, and, finally, to the peritoneum.

A Unique Affection of a Nerve is reported in the *Trans. of the Med. Chirurg. Soc., London* (vol. xlix. p. 29). "An arterio-venous cyst was found in the popliteal nerve," after amputation of the thigh.

Infusion of Coffee in Strangulated Hernia.—The administration of infusion of coffee (℥ iij. freshly roasted and ground coffee, to five cups of boiling water) induced spontaneous reduction in a case of strangulated hernia which had been doomed to operation.—Dr. A. Burillon. *Bull. de Thérap.*, lxxii., p. 82, Jan. 30, *Lancet*, Mar. 16. *Half Yearly Abst.*, xlv.

Treatment of Gonorrhœa.—Dr. Dyes (*Schmidt's Jahrbücher*, No. 2, 1867) says: "Copaiba, it is known, does harm at the commencement of gonorrhœa; it does but little good after the inflammatory stage has passed off. It is almost incredible how practitioners, who throughout the whole course of gonorrhœa order abstinence from everything likely to cause irritation, can, in direct opposition to this, prescribe a medicine so irritating to the kidneys and urinary passages as balsam of copaiba." His treatment consists in subduing inflammation of the urethral mucous membrane by soothing, mucilaginous, and cooling medicine, combined with a spare diet and rest, and directly after the removal of this inflammatory condition, an injection of zinci sulph. is applied to the urethra.

M. Luc, in the *Brit. Med. Journal*, March 23, recommends a tolerably thick solution of starch in acute urethritis. "It never produces pain, and avoids strictures."

Pepsin in the Vomiting of Pregnancy.—A number of French physicians declare the efficacy of pepsin in the vomiting of pregnancy. It should be given in the dose of eight or ten grains, before eating. Hydrochloric acid is also recommended as equally efficient—thirty to sixty drops to be taken daily, properly diluted. Strychnia, we think, is not inferior to either, the twentieth to the twelfth of a grain three times a day.—*Pacific Med. and Surg. Jour.*

Ratio of Deaths from Inhalation of Chloroform.—Edmund Andrews, M.D., in a letter to the *Chicago Med. Enquirer*, states that he has been at some pains to discover the ratio of deaths from the inhalation of chloroform. The surgeons of London do not seem to be fully aware of the real mortality attending its administration, Mr. Simon even expressing the opinion that it is safer to take chloroform than to take a ride in a railroad car. Figures have been collected from fourteen hospitals in Liverpool and London. Reliable accounts of chloroform being administered 83,059 times were obtained, and of these 24 proved fatal, or 1 in 3,461. A railroad in active business with a mortality like this would kill from 500 to 3,000 passengers every year. Dr. Andrews advises the use of ether, reserving chloroform for those who do not come under the influence of ether. Possibly the tetrachloride of carbon may prove to have the safety of ether and the promptness of chloroform. The statistics above given were gathered from surgical cases, and are of no value in testing its safety in obstetric practice.

Enlargement of the Colon.—Dr. Wm. Sewitt, in the *Chicago Medical Journal*, relates the history of a case to which he was called to relieve a patient who had not had an evacuation of the bowels for three weeks. During this time the patient had been in the hands of a *spiritual doctor* who said he was suffering from "*windy dropsy*." The patient was suffering from intense pain in the abdomen, with frequent desire to expel flatus from the rectum, which he could only accomplish by placing himself upon his head and hands in a perpendicular position. The abdomen was enormously distended, and so tense that it was impossible to find the outline of any of the abdominal organs. Since a similar attack about nine years before, he had had a torpor of the bowels, having an evacuation once in eight or ten days. An examination per anum revealed what seemed an enormous tumor, filling the entire pelvic cavity, with a resemblance to a child's head at term. The rectum appeared normal. He had taken powerful cathartics, and copious enemata were ordered, but in attempting to use them they did not pass beyond the rectum, and flowed immediately back. A long rectum-tube was then used, but could not be carried further than the upper portion of the rectum, when it would fold upon itself, showing obstruction at the sigmoid flexure. Laxatives were afterwards used, but to no effect, except occasionally to expel some flatus. He continued in this condition for about a week, when he was suddenly seized with an excruciating pain in the abdomen, and in a few hours expired. An autopsy revealed the peritoneal cavity enormously distended with gas, and a large quantity of fæcal matter, of the consistence of batter, was extravasated into it, showing that perforation had taken place—the immediate cause of death. The perforation was at several points of the colon. The ascending and descending colon appeared like two immense cylinders lying side by side, extending from the epigastrium to the pelvis, being about five and a half inches in diameter, and filled with soft fæcal matter. The two cylinders were folded upon themselves, filling the entire surface of the abdominal cavity. The sigmoid flexure was about the same diameter, and what was supposed to be the tumor filling the pelvic cavity was the sigmoid flexure distended with fæcal matter and folded upon itself, giving the firm and rounded shape of a pelvic tumor, and pressed so firmly upon the upper portion of the rectum as to prevent all passage of fæcal matter into it. The colon was very much thickened, and completely filled with fæcal matter of the consistence of batter, containing over a large wooden pailful, besides what had passed through the perforations into the peritoneal cavity.

Venomous Bites.—By J. T. Newman, M.D.—A man was bitten on the right tendo achillis by a rattlesnake, and was found three hours after suffering the most excruciating agonies. The right side was swollen all the way from the heel to the shoulder, pulse varying from 130 to 145, the respiration from 36 to 40, and he also foamed at the mouth, gnashed his teeth, and violent spasms would ensue. Thirty grains of morphia and a gallon of brandy were ordered. He was given five grains of the former and eight ounces of the latter. The swelling was rapidly covering the entire body. At the end of an hour from the time the first dose was given, the same dose was repeated, and also a poultice of stramonium leaves was applied. It could now be plainly seen that the spasms were subsiding. The brandy was then given in doses of four ounces every fifteen minutes. This treatment was kept up for six hours, changing the poultices every half hour. At the end of that time he fell into a sleep lasting four hours. The swelling now commenced to subside. When he awoke the same dose of morphia as first given was repeated. Two ounces of aq. ammoniæ were mixed with an equal amount of brandy, and after two doses of this mixture he slept several hours. Within as many hours he had taken thirty grains of morphia, a gallon of brandy, and four ounces of ammonia. Except at the part bitten, the swelling had almost subsided. It exuded a greenish fluid, which may or may not have been the virus. The patient recovered.—*Chicago Medical Journal.*

CONCERNING PRESCRIPTIONS.

It has become of late a fashionable practice with the apothecaries to sneer at the qualifications of physicians as prescribers. At first sight we might explain this on the supposition that they are too zealous in urging the claims of their specialty, and too fearful of the possibility of their calling being left out in the cold. It is perfectly natural for any class of individuals to have the interests of their trade or profession dearest to their hearts, and so far as this is an element in their dissatisfaction we must stand ready to excuse them. But that is only in part the cause, for their reflections upon our knowledge of and interest in pharmacy are made appallingly apparent when we calmly examine the question.

There is no disguising the fact that the majority of us merit, to no small extent, all the aspersions which the pharmaceutists heap upon us, and that to the respective charges of carelessness and ignorance we have to put in the plea of guilty.

The first of these charges is not difficult to prove. If any one has gratified a curiosity to fathom the mysteries of the doctors' hand-writing, as seen in the books of our apothecaries, he must be struck at first sight with its illegibility. The page of such a volume spread out before him, looks more like one covered with the cabalistic tracings of some astrologist, than the production of the enlightened professional man of the nineteenth century. If he has the time and patience to decipher some names, and guess at the rest, as he must of necessity be forced to do, he will come to another conclusion: that the doctor is withal rather an ingenious letter-former, as well as an accomplished abbreviator of symbols. This gratification of the inventive faculty would be innocent, even praiseworthy, if it were diverted in a somewhat different channel, where mistakes in guessing and lack of a special genius in appreciating are not apt to be attended with disagreeable, if not dangerous results. When he assumes that the apothecary is a mere person to obey absolutely his directions, and that the patient is supposed to take with unquestioned confidence the different powerful articles that may be written for, he should at least be careful that his meaning is clearly understood. We have no right to throw any extra responsibility upon the compounder of our receipts; and it is more than we have reason to expect that he can always hit the mark, notwithstanding the almost constant practice to which his cleverness is subjected.

The carelessness in writing is in fact one of the main complaints which the compounders have against us; it is justly the crying evil of the prescription-counter, and there is every reason why we should cause it at once to cease One of these gentlemen told us that he actually dreaded to receive some of the prescriptions written by many of his bad-writing patrons, as with most of them he had to waste much valuable time in deciphering, and then not unfrequently was compelled to keep the patient waiting while he despatched his errand-boy, that he might obtain from the writer himself a translation of the important document. This, too, was ofttimes exceedingly difficult when the tracings were over an hour or two old. In this connection he informed us of instances in which the lives of patients were actually saved by the adoption of such a course. Is it not fair then to conclude that he, in common with the rest of his fraternity, had just cause for complaint? These were the gentlemen who were in the habit of scrawling the receipts with very hard lead pencils on the ends of brown wrapping paper and the leaves of old books, and who did not seem to think that the apothecary had the right to ask anything more of them.

The only explanation why this abuse has not been remedied is perhaps to be found in the very small amount of trouble and slight increase of care required on the part of the writer. If physicians generally would take as much pains in writing their prescriptions as in figuring the items in their bills, no one could fail to understand what was meant.

There is no necessity, however, of enlarging upon this particular point, but we will call the attention of those interested to other faults in prescription-writing. The first has reference to the lack of a sufficient knowledge of pharmacy to enable us at all times to make scientific prescriptions. The majority of us are constantly committing these mistakes, and are day by day laying ourselves open to the deservedly severe ridicule of our druggists. The foundation of all this ignorance rests upon a defective medical education, such as is carried on in most of our medical schools. The only practical familiarity which the students receive of the reactions of any pharmaceutical article is the writing of it in a lecture note-book, while the only remembrance is centred in some bottle containing the specimen which has been passed around the class. The whole study of materia medica, as generally carried on, is a mere effort of memory; and it is not remarkable to find that the different reactions, modes of combination, etc., are occasionally forgotten. The fact that our best prescribers are those

who have some time during their pupilage been at work in the prescription department of some shop, should not have its significance lost upon those who still have opportunities for similar improvement. It is only the occupation of some such position in earlier professional life that can safely secure the practitioner against the repeated occurrence of numerous ridiculous and annoying blunders.

But there is another point connected with prescription writing which deserves at this time a passing notice, and that has reference not only to the correctness of the compounds to be employed, but to their elegance and inviting taste. This is truly an art by itself, and when once mastered is of incalculable value to any one who is called upon to treat such as are tormented with tastes that are fastidious. The great objection which many homœopathic patients have against our system of practice is the administration of our nauseous draughts. We cannot quarrel with these people for any dislike they may entertain towards many of our disagreeably tasting drugs; but we should endeavor, by skilful combinations, by the judicious use of the active principles and the employment of concentrated medicines, to do away with the necessity for complaint. The practitioner who can contrive to give a small dose which shall equal in power a larger one, and at the same time divest it of any objectionable taste, will certainly be preferred to his less thoughtful brother.

There is another light in which this matter of refinement in prescriptions can be viewed, and that is the increased tolerance of those remedies which are made more or less agreeable to the palate. Quinine, cod-liver oil, many of the preparations of iron, and a host of others too numerous to mention, can be administered for long periods when properly combined with aromatics, and the like, when without them the stomach of a feeble patient might be constantly nauseated. If more care were taken to render palatable the remedies prescribed to children, there would be less repugnance on their part to the very name of medicine. Let a child take a grain of quinine in a simple solution, and let the nurse choke it down his outraged throat by dint of holding the little one's nose, and by other little tricks which these tender-hearted females know so well, and a prejudice against anything in the shape of medicine is formed which it requires years to eradicate. The same may virtually be said of those of less tender years, who will, despite their best intentions, enter their natural protest against a nauseous compound.

Many of us do not appreciate the importance of palatable mixtures, and not a few refuse to believe that pharmacy is incapable of dressing up the most noxious agents in the guise of agreeable and even tasty compounds. There is nothing in science that forbids its association with refinement; in fact the customs of the present day demand that they should be inseparable, and the physician who takes the hint can find no more difficulty in keeping his patients in good humor, in preventing the formation of wry faces, and in saving his medicines many hard names, than he has in the majority of cases in curing the sufferers of their maladies.

The remarks concerning the remissness of the Board of Health which we have recently made, we are happy to inform our readers were founded upon a misapprehension of the facts of the case. Since writing them, we have received a letter from Dr. Dalton, the Sanitary Superintendent, which presents us with an official statement of the doings of that Board, and which most effectually explains away the reasons for our strictures. We are informed that the Board is still doing its whole work, that the sanitary inspectors are as faithful in the performance of their duties as ever, and that the reports referring to the existence of unabated nuisances, although founded on fact, are really unavoidable, inasmuch as it has been found impossible, on account of the immense number of complaints on hand, to attend to them with that despatch that is desirable. We are glad to hear this, and to be assured that we have been in error in supposing that the delays were due to any dereliction on the part of the inspectors, but rather to circumstances over which the Board itself has no control. We shall soon take occasion to refer more in detail to the workings of this body, and to the obstacles which oppose its praiseworthy efforts.

We have been compelled, on account of a press of material, to defer to the next number an interesting lecture by Prof. Loomis, and an elaborate and finished article by Prof. Joseph Jones, of Nashville.

Reviews and Notices of Books.

The Physiology and Pathology of the Mind. By Henry Maudsley, M.D., Lond. D. Appleton & Co., 443 Broadway, N. Y. 1867. 8vo., pp. 442.

This very important work treats of mental phenomena from a physiological, rather than a metaphysical point of view, and brings the many instructive instances presented by the unsound mind to bear upon the obscure problems of mental science. The physiology and pathology of the mind have, indeed, been too long divorced; and it is time some effort should be made to reconcile these two branches of science. Metaphysical writers have gone on treating mental diseases as pure abstractions, as having no connection with the organization, as if, in short, they belonged to a science which is entirely distinct from that which is concerned with the sound mind. To the medical profession, chiefly, belongs the great credit of exploring and discovering the physical conditions of mental function, and the relation of the phenomena of the sound and the unsound mind. Notwithstanding the great advance that has been made in modern times in the science of mind, some of our teachers of mental philosophy still inculcate the absurd doctrine, that we are acquainted with mind and body as two distinct and separate entities, as if they were separate subjects of investigation; either not connected at all, or only in a very remote and unimportant degree. Our clergy, who generally found their moral and spiritual inculcations on the same false basis, are often

horrified at the sinfulness of a sleepy congregation, who are breathing an atmosphere containing fifty per cent. of carbonic acid. They talk of the faculties and dispositions of the mind without the slightest apprehension apparently, that they are in close connection with the body. A perusal of the memoirs of Edwards, Payson, and other celebrated divines, who speak of their varying moods, dispositions, and feelings, as wholly influenced by supernatural and never by physical influences, must satisfy every person of the general truth of this remark.

How often must the fact be enforced, that the human mind, as it exists in this world, cannot, *by itself*, become an object of philosophical investigation; that, placed in a material world, it cannot act, or be acted on, but through the medium of an organic apparatus? The physician sees the most abundant proof on every hand, that the state of the physical organs exerts a commanding influence over the mental manifestations, and he needs no argument but daily observation to satisfy him that no system of mental philosophy is entitled to consideration which overlooks or denies their influence, and treats the thinking principle as a disembodied spirit. We must take man as he exists in this world, and carefully investigate the laws which regulate the connection between the organs and the mind, not expecting to discover the essence of either, or the manner in which they are united.

This work of Dr. Maudsley is unquestionably one of the ablest and most important on the subjects of which it treats that has ever appeared, and does infinite credit to his philosophical acumen and accurate observation. No one has ever more successfully exhibited the discordant results of metaphysical, physiological, and pathological studies of mind, or demonstrated more satisfactorily the uselessness of an exclusive method, or the pressing need of combined action, and of a more philosophical mode of proceeding. The work consists of two parts; the first part, resting on the physiological method of inquiry into mental phenomena, treats under nine different chapters of "The Method of the Study of Mind;" of "The Mind and the Nervous System;" of "The Spinal Cord and Reflex Action;" of "The Sensory Centres and Sensation;" of "The Supreme Cerebral Centres and Ideation;" "On Emotion;" "On Volition;" "On Actuation;" and "On Memory and Imagination." One hundred and ninety-four pages are devoted to the discussion of these subjects. Many of the views presented are similar to those laid down in the recent writings of Herbert Spencer, Dr. Laycock, and Dr. Carpenter, and with which the readers of the RECORD are doubtless more or less familiar.

Our limits, however, much to our regret, oblige us to pass on to the second part of the work, which treats of the *pathology of mind*, under the following heads: "On the Causes of Insanity;" "On the Insanity of Early Life;" "On the Varieties of Insanity;" "On the Pathology of Insanity;" "On the Diagnosis of Insanity;" "On the Prognosis of Insanity;" and "On the Treatment of Insanity."

In regard to the alleged *causes of insanity*, we have, with the author, always considered them as so vague and general, as to render it extremely difficult to ascertain, with any precision, what they really are. The uncertainty springs from the fact, that in a great majority of cases there is a concurrence of conditions, and not one single effective cause. All the conditions which conspire to the production of an effect are alike causes, alike agents; and therefore, all the conditions, whether in the individual or in the circumstances in which he is placed, which in a given case coöperate in the production of disease, must alike be regarded as causes. Hence, we have looked upon the assigned causes of insanity, as contained in the annual reports of our superintendents of Insane Asylums, as not only worthless, but worse than that, false and deceptive. They would have us believe, forsooth, that a patient has become insane from grief, from anxiety, vanity, ambition, religious excitement, despair, etc., as if these, frequently only the early symptoms of mental disease, were its true and real causes! The fact is, that the causation of insanity may often extend over a lifetime, and its germs are latent in the very foundations of the character, the final outbreak being perhaps only the explosion of a long train of antecedent preparations. There are successive links of causation, sometimes traceable, sometimes not, as the inevitable consequence of certain antecedents; it is palpably absurd to assign mental derangement to the influence of any single cause. It is common to treat of the causes of insanity as physical and moral, but it is manifestly impossible to discriminate them with any tolerable exactness. The truth is, that every moral cause operates through the physical changes which it produces, and in the great majority of cases in which the cause is considered as moral, there is something in the physical constitution by the coöperation of which the result has been brought about.

Our author notices one fact which deserves serious consideration, and which is as applicable to our own country as to Great Britain, and that is, the large increase of late years in the number of the insane who have come under care and observation. He quotes the Reports of the Lunacy Commissioners to show that, on the 1st of January, 1849, there were 14,560 patients in the hospitals, asylums, and licensed houses of England and Wales; that six years afterwards, on the 1st of January, 1855, there were 20,493 insane; that ten years afterwards, on the 1st January, 1865, there were 29,425 insane under certificates; and that on the 1st January, 1866, the number had risen to 30,869; thus showing a steady increase of about 1,000 a year, in the insane population of England and Wales, for the last 17 years; an increase far more than proportionate to the population. From the best statistics we can gather, the same disproportionate increase of the insane is true as regards the United States; though something may be due to the large number of cases formerly unreported, but which more stringent legislation has brought under observation, and to the larger number of insane, especially of the pauper class, who are now sent to asylums; and lastly to the prolongation of life in those who have been brought under proper care. Perhaps, also, more people are now thought to be mad than was formerly the case. Besides, our asylums have become so palatial, so desirable as elegant and commodious residences, that they are not only resorted to by those who are not insane, but continue to be the abodes of many after they have recovered, as the most eligible resorts anywhere to be found. In fact, fewer persons proportionately, are now discharged from our asylums, either by death, or by being thought to have recovered, than formerly; hence, one reason for the increase in the number of our insane hospitals.

Passing over the intermediate subjects, for the consideration of which we have no space left in our columns, we come, lastly, to the *treatment of insanity*, in all respects, perhaps, the most important branch of the subject.

We agree with our author, that in no other disease are the difficulties of treatment so great as they are in insanity—difficulties, not only appertaining to the nature of an obscure disease, but increased and multiplied

by the social prejudices connected with it; by the frequent concealment and misrepresentation on the part of the friends of a patient; but, also, by the unsatisfactory character and management of institutions especially established for the reception of insane persons, and the tendency of recent lunacy legislation (we refer particularly to the legislation of our own country), which has overlooked the great class of the chronic insane, now inmates of jails and alms-houses, and provided only for acute and recent cases. We may say of many of our States, as of England, the land is being covered with overcrowded asylums, to which it is designed that the great mass of the lunatic population shall be consigned, irrespective of circumstances or conditions, where they may be kept safely imprisoned and secluded from the public eye, lest the tender sensibilities of friends and relations may be hurt, or their feelings disturbed. Once there, it would seem that the whole object was accomplished, for there is little if any inquiry ever made, whether all is done that can be to secure the best medical treatment of those who are curable, or the greatest comfort of those who are incurable. The persistence with which the superintendents of our insane asylums have recently opposed the separation of acute and curable cases from the chronic and for the most part incurable cases, shows, we regret to say, a determination to resist all innovation, however desirable, and however beneficial to the insane it may promise to be, and however supported by experience, reason, or weight of authority. Very slight observation must satisfy us that there is at this time, and in our country, a public jealousy of asylums and those who superintend them, which will require a wise and cautious management to overcome. The cruelties of former years yet live in the public memory; and though to be rid, at any cost, of the offending presence of the insane, may satisfy the false views and perverted feelings of some, yet there is an enlightened public conscience, and a right moral feeling regarding this unfortunate class, which will hold those who have charge of them to a strict personal responsibility. To be called a lunatic, is too often equivalent to being cut off socially from all humanity, and those in charge of asylums are strongly tempted to be satisfied if they render their establishments secure prisons and lock-ups. Indiscriminate sequestration seems to embody all requirements; and all treatment, moral and physical, ends in proper classification! Untold evils have arisen from the assumption, that because a man is disturbed in his intellect, he must, therefore, be shut up in an asylum; whereas the true principle to guide our practice should be, *that no one, sane or insane, should ever be entirely deprived of his liberty, unless for his own protection, or for the protection of society.* We therefore fully agree with our author in saying that, instead of acting on the general principle of confining the insane in asylums, and making the particular exceptions, we ought to act on the general principle of depriving no one of his liberty, and of then making the numerous exceptions which will undoubtedly be necessary in the cases of insane persons, as in the cases of criminals. We confine the insane, not as criminals, in order to punish or reform, but to *cure* them, and to protect themselves and society against their violence. Now, no one will deny that there are many chronic and incurably insane persons, neither dangerous to themselves nor others, and who are able, and would be benefited by some light bodily labor, who are at present closely confined in our lunatic asylums, and who ought, by every consideration of expediency and humanity, to be at large. We deny the assumption, so persistently acted upon, that it is no inhumanity to keep them shut up as long as they are insane. Our humane legislation in New York, it is true, causes their removal from our State asylum if not benefited or cured at the end of a year, to those well managed, philanthropic institutions, *county poor-houses and jails*, where they generally remain till death steps in to put an end to their sufferings! But in our other asylums they seem to be kept because they have been once put in—properly, necessarily, or not; sometimes, we fear, because it is thought their existence should not be known to the world; and often to save trouble, care, or expense! If the principle of *non-restraint* in asylums is so admirable and beneficial as all attest it to be, how vastly more beneficial would be the abolition of the restraint of asylums themselves, as in Belgium? Such is the sage suggestion of Dr. Maudsley.

In the statements and principles above laid down, we have only followed in the steps of our author, who has given every one of them the sanction of his authority.

It is not proposed by Dr. M. to leave the insane not in asylums without proper care and control, but to have them provided for in private families, as in Scotland and Belgium. No one can properly appreciate the strength of the passion for liberty which there is in the human breast, even in the insane; and "there is no one," says our author, "who would not infinitely prefer a garret or a cellar for lodgings, with bread and water only for food, than to be clothed in purple and fine linen and to fare sumptuously as a prisoner every day." A slight intercourse with the insane in hospitals must satisfy one that all the comforts they have in their captivity, including games and so-called amusements, are but a miserable compensation for their entire loss of liberty.

Dr. M., it is to be recollected, has himself been a superintendent of an insane asylum, and speaks from ample experience of many years. He thinks the discomforts of these institutions, even the best, are not sufficiently considered; apart from the imprisonment—especially the associations which the insane experience in an asylum where all sorts and conditions of madness are congregated together, harrowing scenes of which they are unwilling witnesses, the vulgar tyranny of ignorant attendants, which is unavoidable in large asylums, and the thousand other unpreventable miseries of asylum life—Dr. M. thinks that the superintendents of asylums are apt to be blinded to the demerits of the system, and in the pride of success of organization, classification, etc., to overlook the numerous evils inseparably connected with it.

The system of placing the pauper insane in private families in Scotland has been tried for several years past, as shown by the reports of the Scotch Deputy Commissioners in Lunacy, and has proved very successful. A few years ago, it is stated, their persons were in a wretched state, neglected and ill-treated in many cases, but that now all this is changed; that by the powerful agency of official instruction and inspection, systematically exercised, all who have to do with them have been penetrated with more enlightened views, and the condition of their charges has accordingly been immensely improved, and now leaves little or nothing to be desired; and what has been done in Scotland can be done here. Besides, the experience of the Scotch Lunacy Board shows that many pauper patients are well taken care of in private dwellings at less than one-half what the cost would be in a county asylum. The condition of the numerous insane Chancery patients in England, who live in private houses, is said to be eminently satisfactory, much more so than it could be in the best asylum, and the same is said to be true of many other single patients living in private families; especially in the village of Hanwell and its neighborhood.

In conclusion, Dr. M. is persuaded that future progress in the improvement of the treatment of the insane lies in the direction of lessening their sequestration and increasing their liberty. Many chronic insane, incurable and harmless, will be allowed to spend the remaining days of their sorrowful pilgrimage in private families, having the comforts of family life, and the priceless blessing of the utmost freedom that is compatible with their proper care. The one great impediment to this reform at present undoubtedly lies in the public ignorance, the increasing fear, and the selfish avoidance of insanity. When knowledge is gradually made to take the place of ignorance, and familiarity banishes the horror bred of ignorance, then will a kindly feeling of sympathy for the insane unite with a just recognition of their own interests, on the part of those who receive them into their houses, to secure for them proper accommodation and good treatment; then also will asylums, instead of being vast receptacles for the concealment and safe-keeping of lunatics, acquire more and more the character of hospitals for the insane, while those who superintend them, being able to give more time and attention to the scientific study of insanity, and to the means of its treatment, will no longer be open to the reproach of forgetting their character as physicians, and degenerating into mere house-stewards, farmers, or secretaries.

THE PHYSICIAN'S VISITING LIST FOR 1868. Phila. : Lindsay & Blakiston.

THIS convenient pocket companion at once commends itself to our notice for its simplicity of arrangement. The publishers have exhibited admirable judgment in the omission of various details, which tend to encumber rather than add to the value of vade-mecums of this kind.

ELEMENTS OF MEDICAL CHEMISTRY. By B. HOWARD RAND, Prof. Chemistry in Jefferson Medical College. Phila.: T. Ellwood Zell & Co. 1866. Pp. 399.

THE volume before us is a "multum in parvo," and well adapted for the needs of the medical student. The definitions are models of pith and brevity, and the book as a whole meets with our approval, especially for the happy manner in which general principles of chemistry, as applied to medicine, are discussed.

MICRO-CHEMISTRY OF POISONS, including their Physiological, Pathological, and Legal Relations, adapted to the use of the Medical Jurist, Physician, and General Chemist. By THEO. G. WORMLEY, M.D., Prof. of Chemistry and Toxicology in Starling Medical College, and of Natural Sciences in Capital University, Columbus, O. With 78 Illustrations upon Steel. New York: Baillière Bros. 1867. Pp. 668.

THE title of the work will give our readers a fair idea of its contents, but as to the nature of these contents it becomes our duty to speak. The volume is of such a size, and the subjects treated of so numerous, that we cannot in the space allotted us give it a full review. Yet we hope that in this necessarily brief notice we shall do it that justice which its intrinsic merit deserves.

The subject of poisons will always be an interesting one to medical men, and any work that is specially calculated to unravel the mysteries which hang over the commission of the most atrocious of all crimes, should be and will be held in special esteem as a positive and important addition to our already too scanty knowledge of toxicology. The only popular works that we have heretofore had upon this particular department of medical science have been those of Taylor and Christison, which are both excellent of their kind, but so far do they fall short of the treatise in question, as regards its particular design, that hereafter it must be considered the authority in the English language. With an industry that has been untiring, and a perseverance truly remarkable, the author gives us in this volume the results of the most elaborate and careful investigations into the nature of most of the known poisons, bringing to his aid the microscope to help him beyond the sphere of the mere analyst, thus enabling him to discover the existence of poison in the 100.000th part of a grain. While he gives to us all that has heretofore been known practically concerning the detection of poisons, mineral and vegetable, he has added many other original investigations which, considering the care that has been taken in carrying them out, give them an immense value, and stamp them rightly with the unquestionable reliability of scientific accuracy. At first the author tells us that his idea was merely to present the results of his studies in the micro-chemistry of poisons proper, but wisely reconsidering his original intention, he has given besides a more or less complete treatise upon toxicology proper, embodying under each appropriate head, the symptoms, treatment, post-mortem appearances, and reactions of the different poisons.

In the appendix we have some seventy-eight superb illustrations upon steel, of the microscopical appearance of different toxic agents. These were faithfully traced by the skilful hand of his wife, who, for the sake of doing her part of the work, studiously set about to master the art of steel engraving. In point of artistic finish and minuteness of detail, we have never seen anything to equal these truly beautiful plates, the excellences of most of which are only appreciable with the aid of a magnifying lens. As a reward for the faithful performance of such a task, the author has, with singular good taste, dedicated the work to her to whom he owes so much. In addition to this, there is a valuable tabular statement of the reactions of the different poisonous alkaloids.

The great value which this work will possess to the medical jurist, the toxicologist, the general chemist, and the lawyer, will be the knowledge that it has been prepared by a most earnest worker, an accurate observer, a practical chemist, and a skilful microscopist, for such, at least, we have reason to judge him to be after a careful study of his masterly work.

CHEMISTRY. By WILLIAM THOMAS BRANDE, D.C.L., F.R.S., L. & E., of her Majesty's Mint, Member of the Senate of the University of London, etc., etc.; and ALFRED SWAINE TAYLOR, M.D., F.R.S., Fellow of the Royal College of Physicians of London, and Professor of Chemistry and Medical Jurisprudence in Guy's Hospital. 2d American Edition, thoroughly Revised. Phila.: H. C. Lea. 1867. 8vo., pp. 764.

THERE are so many excellent works on chemistry now before the public, that it is hard to say which one of them has most claims for favor. The one before us, which is the joint labor of two of the greatest minds in Great Britain, can most certainly demand for itself the highest rank in the special department of which it treats. Although a work of large size, being an octavo of over seven hundred pages, it is filled with such subjects as are useful to the student of every-day chemistry, or to the practical man who measures the utility of every scientific fact in proportion to its capability of being demonstrated. In other words, it is calculated in our opinion to give to the medical man the broadest possible ground-work for the study of chemistry, and the application of its great truths to the every-day necessities of practical life. Nothing more is attempted, and nothing more is needed, in a work specially designed for medical practitioners and stu-

dents. The very rare substances which are only met with in the laboratory of the professor or the cabinet of the amateur, are wisely ruled out, and their places occupied by accounts of more useful, because more common substances. The work has been thoroughly revised by Prof. Taylor, upon whom, by the recent death of his colleague, the whole labor has necessarily fallen. The old systems of nomenclature are adopted, and everything is done in the work to make the road, difficult in all cases to the acquisition of true knowledge, as easy and as gradual as possible.

A Treatise on Emotional Disorders of the Sympathetic System of Nerves. By William Murray, M.D., M.R.C.P., Lond., Physician to the Dispensary, etc., etc. New York: A. Simpson & Co. 1867. 8vo., pp. 95.

The subject treated of by our author is rather a novel one, and he deserves, at least, the thanks of medical practitioners in general for dressing up old facts in new garbs, and explaining by a very plausible theory the relations of mind to matter. He charges, with a fair show of reason, most of the mischief in the shape of morbid emotions, to the agency of the great sympathetic. His remarks upon the influence of emotion in producing disease on the one hand, and as the result of disease on the other, are not, it is true, very new, but they are of so practical a character, and the facts are so suggestive and significant, that the author, it seems to us, has been fully justified in writing such a book. His style is concise, pleasant, and frank, while the number of illustrative cases that are scattered through the *brochure* seems to impress indelibly upon the minds of his readers the facts he wishes to bring out. We are sorry, however, to see this otherwise excellent book marred by such a number of typographical errors, showing inexcusable carelessness in proof-reading.

Correspondence.

THE LIQUOR ZINCI CHLORIDI IN GONORRHŒA.

To the Editor of the Medical Record.

Dear Sir—I am not quite sure that I understand the ground upon which my good friend, Dr. Batchelder, takes me to task in your issue of October 15, in a communication with the above heading. It cannot be for the reason that I have called the chloride of zinc a caustic, since it is commonly so regarded, and not to call it so might even be looked upon as "singular." I suppose, therefore, that Dr. B. refers to my statement as to the strength of the solution of this agent which he is in the habit of using in the treatment of gonorrhœa, especially as I could never understand how his patients always got well under so strong an injection as he employs, while mine often could not bear it at all. Since this matter (not puriform, but merely serous) *is not personal* either to the Doctor or myself—for I could never have any personal difficulty with a man whom to know is to honor and respect—and since there are one or two points of practical interest involved, you will perhaps allow me space for a brief reply.

The statement in my work on Venereal Diseases, to which Dr. Batchelder takes exception, is the following: "Dr. Batchelder dissolves 3 ij. of the chloride (of zinc) in 3 iij. of water, and directs the patient to commence with three drops of the mixture to a tablespoonful of water, and inject three times a day; to add a drop at a time (rarely exceeding eight drops) until a smarting sensation is produced, and then gradually to diminish the strength until the discharge disappears." This statement, my friend says, is "a most singular mistake or misunderstanding in regard to my (his) use of the chloride of zinc."

Now, you know, one naturally does not like to be accused of mistake or misunderstanding when one knows he is right; so you will pardon my saying that the above statement was written down one evening, some ten years ago, directly after I heard it from Dr. B.'s own lips, at a meeting of the New York Medical Association, when, with pleasure and profit, we younger members used to listen to the results of his mature experience. This very note is now before me, including Dr. B.'s remarks upon the treatment of bubo by his favorite remedy, compressed sponge, and of swelled testicle by an emetic of tartarized antimony and the local application of mercurial ointment.

But, from fear that some will-o'-the-wisp might have transmogrified my notes during the ten years they have been lying on my shelf, I have to-day borrowed the volume of records of the New York Medical Association, from the present Secretary, my friend Dr. A. E. M. Purdy, and I find there abundant testimony that my estimate of the strength of the solution employed by Dr. B. is, if anything, below the average statement made by himself in several communications to the society. Thus, at the session of February 11, 1856, when the treatment of gonorrhœa was under discussion, Dr. B. is reported by the Secretary, Dr. Leaming, as saying that "he uses the chloride of zinc and distilled water *equal parts*, and eight (8) drops of this solution to an ounce of water" as an injection.

But this evidence is superfluous, since Dr. B. confirms my statement in the very communication to your journal in which he calls me to account; with this exception, that the injection he now uses, viz., six drops of the liq. zinci chloridi to the ounce of water, is one-tenth stronger than the one I quoted!

Several years ago, at my request, Prof. P. W. Bedford, of the College of Pharmacy, made a careful estimate of the specific gravity and number of grains of the chloride in each fluid drachm of the liq. zinci chloridi, for the purpose of facilating the writing of prescriptions for dilutions of this fluid. The same gentleman has made a similar examination of a solution of two drachms of the chloride of zinc in three drachms of water, and the following are the comparative results:

"The liq. zinci chloridi, as sold by Dr. Squibb, has the sp. gr. 1.56. A fluid drachm weighs eighty-eight and one-half grains, and contains forty-four grains of anhydrous chloride of zinc. *Drops are totally unreliable*, and may vary from one hundred and fifty to fifty-eight to the fluid drachm; but it is safe to estimate them on the average at sixty-four (the result of twenty trials). Hence six minims or six drops may be calculated to contain four and four-tenths grains.

"Again, if two drachms of chloride of zinc be dissolved in three drachms of water, we shall have a solution measuring three and three-fourths fluid drachms, with a sp. gr. of 1.41. Each fluid drachm weighs eighty grains, and contains forty grains, or every six drops four grains, of anhydrous chloride of zinc. Hence this solution is one-tenth weaker than the liq. zinci chloridi."

When, therefore, my venerable friend says that his "injection in gonorrhœa is simply six drops of the liquor zinci chloridi to an ounce of water," he simply says that his injection is one-tenth stronger than if he used three drops of a solution consisting of zinci chloridi 3 ij. and aquæ 3 iij., to half an ounce of water. Q. E. D.

Mr. Milton, who appears to have tested the efficacy of various caustics and astringents in the treatment of gonorrhœa with a great deal of care, assigns to the chloride of zinc a position inferior to that of the sulphate and acetate; and such, as a general rule, has been my own experience, although in some exceptional cases the chloride will succeed when the sulphate and acetate fail. I have not usually been able, however, to use so strong a solution as that recommended by Dr. Batchelder.

In closing, I would merely call attention to the uncertainty and inaccuracy of prescribing drops instead of minims.

Very truly yours,

F. J. BUMSTEAD.

162 West Twenty-third street, Oct. 22, 1867.

THE COLLEGE COMMENCEMENTS, PHILADELPHIA.—THE PHYSICIANS AND APOTHECARIES.

(FROM OUR OWN CORRESPONDENT.)

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—On Monday, 14th ult., the sessions began in the medical colleges of this city. At noon the introductory at the University of Pennsylvania was delivered by Prof. LEIDY in a brief, practical address, detailing the method of tuition pursued at the institution, and giving the students some excellent suggestions as to the manner of study. The importance of attendance upon clinical instruction was pointed out, and the advantages of an acquaintance with French and German were prominently set forth. At half-past seven in the evening, the general introductory at the Jefferson Medical College was delivered by Prof. Gross. This was anything but a brief address, but the subject selected was one so extensive as to preclude the possibility of brevity in doing it justice. The changes which had taken place in practice, and the improvements which had been made in the science and art of medicine since the lecturer's first entrance into the profession, and embracing a period of forty years, was the main subject presented. The audience upon each occasion was very large, and at the more convenient evening hour the room was literally packed, numbers standing at the entrance for whom there was no accommodation inside. It is impossible to judge from the attendance upon an introductory of the number of students present in regular attendance, as members of both classes attend indiscriminately, as well as graduates and friends of the institution. It is believed, however, that the classes are fully equal to the numbers of last year.

The subject of the reciprocal duties between physicians and apothecaries was discussed at several meetings of one of our medical societies, previous to their annual adjournment over the summer months, and it is again receiving considerable attention. Many grievances, on the part of a certain class of apothecaries in this city, have been gradually accumulating for years, until at length physicians are compelled to concert some measures of relief for their own protection. An indisposition to move actively in the affair, and a dislike to be the first one to make the movement, has long held each one back, but the matter is now being discussed in earnest, and it is to be hoped that the result will be satisfactory.

It is not only that apothecaries' stores have become, in many instances, degraded into confectionery, stationery, perfumery, and dram shops, but that the proprietors of these establishments are taking upon themselves certain functions of the physician which were not surrendered to them when he abandoned the preparation of his own prescriptions. Such are, prescribing for the sick and thereby diverting from the physician a portion of his livelihood; the substitution of one ingredient for another in putting up prescriptions; the criticism of prescriptions before patients; the appropriation of the formula of a physician, and the vending of the remedy, either privately or by advertisement, as a proprietary medicine. These, and other abuses, as the exposal for sale of such remedies; the renewal of prescriptions against the wish of the prescriber; the recommendation of one physician to the detriment of another who is in attendance upon the case, etc., are calling for some method which shall remedy the evils complained of. One plan strongly urged, is to patronize only such apothecaries as restrict their business to the compounding of prescriptions and sale of drugs. There are a number of trustworthy pharmaceutists who are at present compelled, by the press of competition, to offer for sale certain family medicines, and perhaps otherwise transgress their proper limits, who, if assured of the support of practitioners, are willing at once to abandon all the practices complained of. It is therefore recommended by some physicians that such concerted action be made general, and that every prescribing apothecary be prosecuted for practising without a license, and that all apothecaries vending secret remedies or quack medicines be declared unworthy of confidence in the compounding of prescriptions. Whether anything will be done remains to be seen. Physicians have it in their power to correct these abuses if they will act together, and the best method of doing so is to make up their minds to direct their patients to such pharmaceutists only as confine themselves to a legitimate prescription business. Should any action be taken by the society which is now agitating the matter, they will doubtless invite the coöperation of the other medical societies and the profession at large in the city. If anything definite is determined upon I will inform your readers of it, unless, indeed, some objection to publicity be made, which is not unlikely to occur.

Yours truly, C. J.

Philadelphia, Nov. 1, 1867.

CREASOTE FOR BURNS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—We are surprised to find creasote as an application for burns referred to in several of the journals as a new thing. It has, for several years, been so generally and successfully used in this city, both in hospital and private practice, that we supposed its value was more extensively known. If we were mistaken, let us add our testimony to its merit. We dilute the creasote with water till the mixture has but slight milkiness remaining; or, to be more exact, ℞. Creasoti ʒ iij.; aquæ font. Oj., M. In dressing burns it is of great importance to the patient's comfort that the strips of old linen or cotton, by means of which the application is made, should not be more than two inches wide—that they may be renewed successively without disturbing a large surface at once. Yours truly,

J. H. HOBART BURGE.

60 Court Street, Brooklyn.

A THEORY REGARDING THE CAUSE OF PHOSPHORESCENCE.—A French savant has propounded the theory that phosphorescence is due to the emission of light previously absorbed. He finds that porous substances that have been exposed to light have a decomposing action on salts of silver, when placed in contact with them in the dark.

New Instruments.

A NEW PESSARY.

By M. S. BUTTLES, M.D.,

ADJUNCT TO CHAIR OF OBSTETRICS, AND PRELIMINARY LECTURER ON GYNÆCOLOGY, IN UNIVERSITY MEDICAL COLLEGE, NEW YORK.

In the Medical Record of August 1, 1867, mention is made of a pessary exhibited by me at a meeting of the East River Medical Association.

Since then I have been so frequently interrogated by members of the profession (some having very erroneous and almost ludicrous ideas) in regard to its use, that I have thought it best to make known, in a few words, some of the advantages of this instrument, with directions when and how it is to be used. In the first place we wish to state that we do not make the subject of pessaries our hobby, and ride it to death; but that they are sometimes of use, no enlightened physician will pretend to deny.

Recognizing the principle that the uterus is mainly supported by the vagina and muscular tissues of the pelvis, it is easy to see why a foreign body introduced into the vagina ought to be supported in the same way. The uterus is a cone with the apex down; the contractility of muscular tissue and coaptation of the soft parts tend to slide the uterus up in the pelvic cavity; should the base of the cone be placed down, the same cause would very soon force the organ into the external world.

It is upon this principle that we have constructed the "conical pessary." It is made of hard rubber, and may be bent to any curve by simply oiling and passing through a flame until it becomes softened.

Fig. 1.

Fig. 2.

The accompanying cuts will convey an idea of its shape better than I can explain. Figure 1 represents a front view, while figure 2 shows its relation to the uterus in cases of prolapsus, retroversion, and retroflexion, the base being in the posterior vaginal *cul-de-sac*. In cases of anterior displacements, the base of the instrument should be placed anterior to the cervix uteri, and in all cases the apex should float loosely in the vagina (sometimes being visible at the vulva) so as to participate in the downward movement of the uterus when the patient coughs or strains.

It is a great mistake to attempt the support of the uterus by a dead pressure, especially if there exists the least inflammation or irritability of the organ. There is nothing like nature's support—the soft parts.

We have been informed of a case where the instrument was introduced with benefit by placing the apex in the posterior *cul-de-sac*, and the base against the inner surface of the ascending rami of the pubes. This was done by a very highly educated physician of this city, who has attained considerable eminence as a gynæcologist, and one for whose judgment we have the most profound respect.

If the instrument is introduced in this way it does not act on the principle upon which it was constructed, and falls short of what is designed.

What we claim for this pessary is, that it brings into play the natural supports of the uterus, and can be worn by the patient when other instruments cannot; that it is more effectual in keeping the organ *in situ;* that where congestion and irritability exist as the result of displacements, it is not always necessary to treat the uterus before introducing it, and removing the cause.

It may be used with great benefit in the anterior displacements; but experience shows that it is more effectual in cases of prolapsus, and eminently so in posterior displacements.

In justice to our friend, Dr. James E. Steel, we will state, that while conversing with him, some two years ago, we gained an idea which contributed in a measure to the result of this invention.

Medical Items and News.

Address before Alumni of University.—Professor George T. Elliot will deliver an address before the Alumni of the Medical Department of the University, on Friday evening the 22d inst., at 8 o'clock, in the large chapel of the University on Washington square. The profession generally are invited.

The "Howard Ambulance."—A recent letter from Baron Larrey announces the awarding of the silver medal to Dr. Benjamin Howard, of this city, by a unanimous vote of the International Council, and requests drawings and descriptions, which may be laid before the Academy and the Army Medical Boards by the Inspector-in-Chief of the Medical Deparment of the armies of France.

Long Island College Hospital.—Prof. Jos. C. Hutchison has resigned the chair of Surgery, and Prof. E. N. Chapman that of Obstetrics, in the Long Island College Hospital.

Surgeons to the Queen.—Sir W. Fergusson has recently been appointed Sergeant Surgeon to the Queen, and Mr. Paget, Sergeant Surgeon extraordinary.

Assistant-Surgeon James M. Flint, U. S. N., has been detached from the Pensacola, and is waiting orders.

Dr. Marion Sims has been honored by the King of Italy with the title and insignia of Knight of the Order of St. Maurice and St. Lazarus. He is now also Commander first-class of the Order of Isabella la Catholique.

Dr. Alfred O. Treat has sailed from New York *via* California as missionary-physician to Pekin, China.

Dr. Levi Folsom died in this city, October 25, ult., aged sixty-four years, ten months, and twelve days.

RECENT APPOINTMENTS IN THE U. S. ARMY MEDICAL DEPARTMENT.—Drs. Samuel H. Orton, A. B. Campbell, John N. Randall, W. J. Wilson Jenkins, A. Fitzgerald, Peter Moffat, Charles Styer, Joseph H. T. King, Joseph K. Corson, Alfred Delano, W. H. H. Michler, Daniel Weisel, and Peter J. A. Cleary.

DR. D. TILDEN BROWN has been appointed Professor of Psychological Medicine and Medical Jurisprudence in the College of Physicians and Surgeons in this city.

DR. THOMAS N. GETTY, Brevet Lieut.-Colonel, U. S. A., Post Surgeon at Fort McHenry, Md., died, aged about fifty years, on Oct. 30th, ult. His original commission as Asst.-Surgeon bears date Nov. 23, 1849. Until within a short time since, Dr. Getty filled the position of Medical Director of the Department of the South.

DR. E. M. SHAW, also of the army, was killed in an attack by Indians upon a stage near Soda Lake, Arizona, October 17th, ult.

DR. JOHN M'GREGOR, late surgeon in a Connecticut regiment, and recently of Thompson, Connecticut, was thrown from his carriage on the afternoon of Nov. 4th, ult., on Dyer Street, Providence, R. I., in consequence of a collision with a freight car drawn by horses. He was run over, and sustained a comminuted fracture of the left arm, which necessitated amputation at the shoulder-joint. He died within three hours after the accident.

DEATH OF JOHN D. MURPHY, PASSED ASST.-SURGEON, U.S.N.—A telegram has been received, announcing the death of Passed Asst.-Surgeon John D. Murphy, U.S.N., at Pensacola, Fla., of yellow fever. Surgeon Murphy entered the United States service November 5, 1861, and was promoted to Passed Asst.-Surgeon, January 24, 1862, being at the time of his death the first for promotion to full Surgeon. During the war, Dr. Murphy saw much active service, being present at the following engagements: Passage of Forts Jackson and St. Philip and capture of the Chalmette batteries below New Orleans, April, 1862; first attack on Vicksburg, June 28, 1862; encounter with the rebel ram *Arkansas*, July 15, 1862; siege and capture of Port Hudson, during which Dr. Murphy was on shore with the battery of nine inch guns from the *Richmond;* skirmish at Mississippi City, March 8, 1862; both attacks on Fort Fisher, N. C. Dr. Murphy was ordered from the naval hospital, N. Y., in the early part of the present year to duty at Pensacola, where his duties have for a long time compelled him to battle with the epidemic to which he finally succumbed. Dr. Murphy stood well in his profession, and his death will be deeply felt by his friends and the service generally.—*Army and Navy Journal*, Nov. 2. [Dr. M. died Oct. 23d ult.—ED.]

THE NEW GERMAN HOSPITAL now being built in Seventy-sixth street, this city, has realized quite a handsome sum—the proceeds of a vocal and instrumental concert at Washington Hall, Morrisania, N. Y. This institution is still somewhat crippled for means, and eminently deserves a recognition of its claims upon the public.

PORTS DECLARED INFECTED.—The Metropolitan Board of Health has adopted a form of proclamation declaring the following Southern ports infected until Nov. 21st: Galveston, Lavacca, Corpus Christi, Indianola, New Orleans, Mobile, Key West, Pensacola, and St. Augustine.

DISAPPEARANCE OF THE CHOLERA FROM PALERMO.—Our Consul at Palermo, under date of October 1, says: The cholera epidemic has entirely ceased in this town, there having been no new cases since the 22d of September last. For the past six days the health officers have issued clean bills of health. The actual number of deaths during the epidemic, as well as I have been able to ascertain, was 4,776 in the city proper, and some 700 or 800 in the neighboring villages. Business is slowly reviving.

DARWIN'S THEORY OF THE ANIMAL SCALE.—Professor Bischoff, of Munich, has recently received numerous skulls of orang-outang, chimpanzee, and gorilla, and comes to the conclusion that Darwin has failed to prove the ascent of man from the monkey.

A LIBERAL LONDONER.—A wealthy Londoner, name not mentioned, has given £250,000 for the erection of a convalescent hospital in London.

DOCTORS CONNECTED WITH THE PUBLIC PRESS.—Twenty-five doctors, all of whom have some time practised medicine, are at present responsibly connected with the New York press.

POPULATION OF GREAT BRITAIN.—Great Britain now contains thirty millions of people, an increase of two and a half millions since 1852, and during the time she has furnished three millions of emigrants to this country, Australia, and other parts of the globe. During the last fifteen years, Ireland has decreased in population nearly eight hundred thousand.

AMONG our French exchanges is a new medical journal which has recently appeared at Paris, and is edited by Professor Piorry. This new medical periodical bears the name of the *Evénement Médical*, and is decidedly an event in the scientific periodical literature of the day. Professor Piorry has at present attained to an advanced age in years and in the memory of the profession. His skilled diagnosis in the clinical wards of his hospital, his lucid expositions of obscurely revealed symptoms of the most perplexing forms of disease, have rendered him preëminently distinguished as a diagnostician. His name will live in history associated with the names of Auenbrugger and Corvisart, and as having contributed largely in practical benefits to our knowledge of the pathology of the interior organs of the body. We sincerely and most cordially greet the appearance of this new journal. The learned professor is a candidate for one of the vacant places left by the death of Rayer and Velpeau. Bonne chance à l'auteur de "Dieu, l'Ame et la Nature."

NEW YORK SOCIETY FOR THE RELIEF OF THE RUPTURED AND CRIPPLED.—During the month of August last, five lots of ground (125 by 100 feet) have been purchased, on the northwest corner of Lexington avenue and Forty-second street, for the purpose of erecting thereon a hospital for the surgical treatment, and education whilst under treatment, of crippled children—many of whom will be detained three or more years for cure. There will also be a department for the treatment of out-patients, furnishing them with surgico-mechanical appliances, and keeping the apparatus in repair whilst under treatment. All this will be free of charge to the indigent; and to those able to pay, a charge will be made to meet their circumstances when so desired. The amount received from patients is handed to the Treasurer of the Society, and contributes to the support of the Institution.

In our present very limited sphere the labors have been as follows:

The number of patients treated the first year was 828; the second year 965, showing an increase of sixteen per cent.; the third year the patients numbered 1,489, or an increase of fifty-four per cent.; and during the fourth year, ending May 1st, there were 1,684 cases, which is equivalent to thirteen per cent.; and the whole

number who had received the benefits of the Institution up to that period was 4,966.

These figures are important and significant. They show, that as the Society grew in public knowledge and favor, there was a large and rapid increase of cases. In the fourth year, however, the increase was only thirteen per cent. over the preceding. This was not owing to a paucity of cases, for of these there was a steady increase, but to the Society's inability to receive or treat a greater number without enlarged means and accommodations.—*Extract from Remarks of Dr. James Knight at the Collation of the N. Y. County Medical Society.*

Death Statistics of the Sexes.—In a paper by Mr. W. L. Sargant, on the vital statistics of Birmingham and seven other large towns in England, results are arrived at different in some respects from those commonly received. Thus, whilst admitting that there are more male deaths on the whole than female, the author states that "in the first five years of life there is a large excess of male deaths; that from five to ten years of age the male excess is very small; that from ten to fifteen the male excess is decided, but at fifteen the tide turns, and until twenty the female deaths are largely in excess; that from twenty to thirty-five the male and female deaths are equal; and then after thirty-five, the male deaths are again in excess. Mr. Sargant adds in a note the "singular fact" obtained from Mr. Makeham, who is such high authority in vital statistics, "that among the *males* of the upper classes, from the age of sixteen to that of twenty-three, the annual rate of mortality rises rapidly from about eight to a maximum of fifteen per thousand, after which it gradually diminishes." It cannot but be desirable and interesting to ascertain the cause or causes of this state of things.

To the Generous Members of the Profession.—Dr. Mong-Shaw-Loo, a native of India, who has been in this country nearly ten years, obtaining an education, and is now a graduate of Lewisburg College, Pa., and of a medical college in Cleveland, Ohio, where he was a student of Dr. Gustav C. E. Weber, is about returning to his native land. Any of our readers who have books or surgical instruments, or apparatus, that they can dispense with, would do a worthy act to a worthy man by forwarding them to this office [115 S. Seventh street]. Dr. Mong-Shaw-Loo will need them in imparting instruction to others in India, where the field is extensive and the laborers are few.—*Phila. Med. and Surg. Reporter.*

Assignments in the U. S. Army Medical Department.—A special order has been issued from the War Department, directing the following newly-appointed Assistant-Surgeons to report for duty as hereinafter indicated: A. B. Campbell and J. H. T. King, to the Medical Director, Department of Dakota; Daniel Weisel, to the commanding officer of Fort McHenry, Maryland; P. C. A. Cleary, to the Medical Director, Department of the Cumberland; W. H. H. Michler, to the Superintendent of West Point, New York, temporarily; John N. Randall, J. K. Corson, and Alfred Delaney, to the Post Surgeon of the principal recruiting depot, Fort Columbus, New York harbor.

Officers of the East River Medical Association.—The following were elected at the Anniversary Meeting of the above Association: President, Dr. John Burke; Vice-Presidents, Drs. William Newman and Robert A. Barry; Secretary, Dr. William J. Purcell; and Treasurer, Dr. Truman Nichols.

Yellow Fever in New Orleans, La.—The New Orleans Board of Health, Nov. 5th, ultimo, after paying a high tribute to the Howard Association in recognition of their disinterested services, declared yellow fever no longer an epidemic The total number of deaths up to above date was 3,006.

Consultations with Homœopathists.—The articles which have appeared in the New York papers lately on this topic, forcibly illustrate how little the public understand the motives which induce medical societies to oppose such a practice. One journal, which is always loud in its claims to liberality and fairness, tells us we do not understand our position—that such opposition is *unphilosophical.* Let us see how this charge stands.

If Mr. Field, when he wished to lay the Atlantic cable, had called to his aid the spiritual media who claim to be able to move matter without human agency, and asked their advice and assistance in the matter, would he have been a philosopher or a fool? If the surgeons in India were to solicit in their cases the powers of the school of native doctors, who cure exclusively by charms and amulets—the Saat, we believe they are called—would they be acting in an eminently philosophical manner? Yet these latter unquestionably are well educated, and tolerably successful; and very intelligent and honest folks have implicit faith in "physical manifestations." To act philosophically, is simply to act in accordance with common sense. There would be no sense or honesty either in advising with a person as to hanging a charm around the neck of a man, when we believe it will have no effect at all—or, if any, merely through his faith in it. To do so would be to encourage an error or a deceit.

Just so with the infinitesimal doses. We firmly believe they are all inert. To consult, therefore, which of them to give, is hypocrisy or knavery—no moderately honest man would do it; one who is openly dishonest has no business in a reputable medical society. If any believe the doses are not inert, and yet cannot subscribe to the "Law of the Similars," such consultations are equally vain, and equally unphilosophical. The wonder is, why any can be found in either camp to court such foolish and aimless interviews.—*Phila. Med. and Surg. Reporter.*

The Cholera at the U. S. Naval Rendezvous, near Philadelphia, has happily been brought under control. The type was pronounced virulent, and the sick men were transferred from the *Potomac*, the receiving ship on board of which it first appeared, to the double-ender *Sassacus*, which was converted into a hospital ship. The first death occurred on board the former ship, which is now dismantled and undergoing purification, October 19th, ult. Surgeons Lowber, King, Wales, Nelson, and Denby, Past Assist.-Surgeon Hutchinson, and Assist.-Surgeons Drennan, Frank, and Hawks, were on duty during the prevalence of the malady.

Births in Vienna.—According to the statistics of last year, the illegitimate births in Vienna exceeded the legitimate by one thousand.

Arrival of Immigrants at this Port.—The statement of the Commissioners of Emigration shows that during the year ending October 30, 1867, 208,428 immigrants arrived at this port.

Suicides.—The London *Athenæum* directs attention to the Registrar-General's curious return of the number of suicides in England during the eight years from 1858 to 1865. They average 1,300 annually, and to every million of the population run thus in each successive year: 66, 64, 70, 68, 65, 66, 64 and 67. Hanging has always been the death generally adopted by suicides, 28 out of the ratio of 67 per million suicides falling under

this head. After hanging follow cutting, stabbing or drowning, poisoning and by firearms. The ratio of suicides per million of the respective population in 1864 was 110 in France, 64 in England, 45 in Belgium, 30 in Italy, and 15 in Spain.

Singular Superstition in England.—"Going into a neighbor's house in Madely, one day last week, I found one of the children suffering from severe cough, and expressed my opinion that it was a case in which medical assistance should be obtained. The father of the boy agreed that it was very bad, but said that before calling in a doctor he intended to try a cure that he had long used in similar cases, and never found to fail. On being pressed to communicate the prescription, he gravely informed me that the charm consisted in cutting a few hairs from the part of the patient's head where it joins the neck, placing them between two thin slices of bread and butter, and giving them to a dog. If the sandwich took no effect on the animal the patient would recover; but if the dog sickened the case was critical, and a doctor should be called in forthwith."—*Pall Mall Gazette Correspondent.*

Poisoning by Phosphorus.—M. Dybkowsky, in a recent memoir, states that the poisonous action of phosphorus is entirely due to the formation of phosphoretted hydrogen gas, which, in passing into the blood, rapidly combines with the oxygen present. Hence that death from phosphorus is nearly he concludes equivalent to death by asphyxia.—*Med. and Surg. Reporter.*

Making Sea-Sand Productive.—Another experiment has been made in England to ascertain the effect of sewage manure upon sea-sand, which, according to Liebig, would never yield a crop. The metropolitan sewage company became tenants of ten acres of land at Barking, upon which bricks had been made. On one acre of the ten, 4,000 loads of the Maplin sands were spread to the depth of two feet. On this grass and wheat were sown, with an admixture of the sewage, and the result was a healthy and productive crop. This year the whole of the ten acres, for which the company paid £1 an acre, is all laid down in grass, and has been re-let to a London dairyman at £13 10s. the acre, the company supplying their tenant with sewage to the amount of 50s. per acre.—*N. Y. Evening Post.*

A Medical Examination in Ireland.—A contributor who has himself been one of the fortunate candidates, sends us the following interesting item:

"The examination for the diploma of the Royal College of Surgeons in Ireland is looked forward to by the students of the Dublin Medical Schools as an ordeal demanding from the candidate not only an intimate acquaintance with professional subjects, but a considerable amount of fortitude and self-possession for the occasion. Before he can present himself for the final examination, the student is arraigned before the Court of Examiners in classics, in order to satisfy the College that he has received a suitable preliminary education; but this step may be taken at any stage of his professional studies. Having attended the prescribed courses of lectures and sessions of hospital practice, he makes application for 'letters testimonial,' and when his turn has come round he presents himself in the building of the college to await the pleasure of the Court of Examiners Things have changed in some minor respects since my time, apart from the well-known addition of practical demonstrations in anatomy and surgery, and the answers in writing now required from candidates. But I will briefly describe the scene as it presented itself to me some six years ago.

"Arriving at the outer door, under escort of Drs. John Morgan and E. D. Mapother, the celebrated grinders, both now professors of the college, with a few friends who had already been through the mill, and a *posse comitatus* of future candidates, the applicant was received by the venerable John Evans, the veteran college porter, who eyed him with an anxious glance, possibly having some connection with the usual fee on delivery of the diploma. After a short interval, occupied by the assembling of the court, a bell was heard to sound, and Mr. Evans, presenting himself at the door of the examination-hall, received the order, 'Bring in the candidate,' and the latter was ushered in by the obsequious John, who pushed the chair well in under him at the table, lest in his trepidation he should lose his balance, and supplied him with a glass of water to relieve any vocal agitation which might arise.

"The candidate now found himself seated at a large round table. Opposite to him he observed Mr. Richard G. H. Butcher, of resection celebrity, President of the Court of Examiners, with a member of the council of the college, and three other examiners on each side to complete the circle. These all retained their respective positions during the examination, and to each of the examiners he was required to give answers distinctly audible to the rest. Fortunately, the remaining audience, consisting of such licentiates of the college as chose to attend, was seated behind the candidate, on tiers of benches at the end of the hall nearer the entrance. He was then examined in succession by each member of the court, the examination continuing for one hour on each of two successive days.

"Among the most trying features of the ordeal was the exhibition by Dr. Jerome Morgan of what poor old Arthur Mitchell used to call the "arcana medicamentorum," consisting of specimens of the materia medica, the name, history, habitat, and properties of each of which were in turn demanded; and the good Doctor seemed well pleased when the fortunate aspirant accurately discriminated between carefully crystallized specimens of Epsom salts, sulphate of zinc, and oxalic acid, and pronounced certain small flakes to consist of the inspissated juice of the momordica elaterium, ecbalium agreste or squirting cucumber, σίκυς αγριος of Hippocrates, commonly found growing wild among the rubbish in villages of Greece and the Archipelago, the specimen being recognized by the impress of the linen on which the feculæ are dried. Various were the questions propounded in anatomy, physiology, practice of medicine, and operative surgery; and Mr. Michael Harry Stapleton (better known to students as 'Baron Larrey,' a sobriquet probably derived from his undisguised admiration of that still more eminent surgeon), inquired into the nature and treatment of common sprains, the different varieties of aneurism and epilepsy, vainly endeavoring to 'take a fall out of' the candidate by suggesting horse exercise as a prophylactic in the latter disease.

"Towards the close of the second *séance*, the candidate was accosted by the still small voice of Mr. Butcher, requesting him in amiable accents to 'write a prescription for a purgative mixture and read it,' which done he retired to the library, or more frequently just outside the door of the hall, to await the result, which was finally communicated by John Evans in the shape of a piece of paper containing the words, 'The court is—satisfied,' with an ominous blank for the addition of 'not,' which frequently, alas! in less fortunate instances, appeared in half-dried ink like the signature of the President, the remainder having been prepared beforehand. The decision was arrived at by ballot of the examiners, and from it there was no appeal, no alterna-

tive but to return to his studies for the space of six months. The final ceremony consisted in making and subscribing to the following declaration: 'I, A. B., do solemnly and sincerely declare and promise, that I will observe and be obedient to the statutes, by-laws, and ordinances of the Royal College of Surgeons in Ireland, and that I will, to the utmost of my power, endeavor to promote the reputation, honor, and dignity of the said college.'

"There are, in Dublin, several schools of medicine and surgery, and although some of them are under the direction of the authorities of the different colleges, the professors are ineligible to the office of examiners. There are four colleges empowered to grant degrees or diplomas, viz., the University of Dublin (Trinity College), the Queen's University, which has no school in Dublin, but holds its examinations at the vice-regal castle, the Royal College of Surgeons, and the King and Queen's College of Physicians, which has a kind of partnership school in connection with Trinity College. There are, besides, several unchartered schools, which have no direct connection with any examining body, in which students are prepared for the different examinations."

MENTAL LABOR AND PHYSICAL EXERTION.—It may be possible, at some future stage of scientific inquiry, to compute the comparative amount of oxidation in the brain during severe mental labour. Even now, from obvious facts, we must pronounce it to be a very considerable fraction of the entire work done in the system. The privation of the other interests during mental exertion is so apparent, so extensive, that if the exertion should happen to be long continued a liberal atonement has to be made in order to stave off general insolvency. Mental excess counts as largely as muscular excess in the diversion of power: it would be competent to suppose either the one or the other reducing the remaining forces of the system to one-half of their proper amount. In both cases the work of restoration must be on the same simple plan of redressing the inequality by allowing more than the average flow of blood to the impoverished organs, for a length of time corresponding to the period when their nourishment has been too small. It is in this consideration that we seem to have the reasonable, I may say the arithmetical, basis of the constitutional treatment of chronic disease. We repay the debt to nature by allowing the weakened organ to be better nourished and less taxed, according to the degradation it has undergone by the opposite line of treatment. In a large class of diseases we have obviously a species of insolvency, to be dealt with according to the sound method of readjusting the relations of expenditure and income. And, if such be the true theory, it seems to follow that medication is only an inferior adjunct. Drugs, even in the happiest application, can but guide and favor the restorative process; just as the stirring of a fire may make it burn, provided there be the needful fuel. There is thus a definite, although not numerically stateable relation, between the total of the physico-mental forces and the total of the purely physical processes. The grand aggregate of the oxidation of the system includes both; and, the more the force taken up by one, the less is left to the other. Such is the statement of the correlation of mind to the other forces of nature. We do not deal with pure mind—mind in the abstract; we have no experience of an entity of that description. We deal with a compound or two-sided phenomenon—mental on one side, physical on the other; there is a definite correspondence in degree, although a difference of nature, between the two sides; and the physical side is itself in full correlation with the recognized physical forces of the world.—*Macmillan's Magazine for September.*

THE NERVOUS TELEGRAPH.—A French savan has likened the quickness of volition in an animal to the telegraph. He tells his class: When a whale is harpooned, the nerve affected instantly telegraphs to the creature's brain, "Harpoon in tail;" upon which the brain telegraphs back, "Jerk tail and upset boat." What a wonderful thing is science!

EXERCISE AND ITS EFFECTS.—Mr. Archibald Maclaren, in a volume entitled "Training, in Theory and Practice," speaks of the immediate effects of exercise on the muscles most actively engaged at the time. He found the law of development strongly demonstrated in a long pedestrian tour, extending over nearly four months, in which the average per day on foot exceeded nine hours, and usually with a knapsack weighing twelve pounds. During this time the chest fell from 41 to 39½ inches in circumference; the upper arm from 14½ to 13¼; the lower arm remaining unchanged at 12½ inches. The lower limbs, on the contrary, were greatly increased—the calf of the leg passing from 16 to 17¼ inches; and the thigh from 23¼ to 25 inches. Often recorded examples to the same purport are seen in the great development of the legs of dancers and the arms of a blacksmith, etc.

EFFECT OF THE ABSENCE OF SOUND UPON THE MIND AND SENSE OF HEARING.—Dr. H. Ralls Smith, of Louisville, Ky., in the course of certain investigations, has established the truth of the theory that the permanent denizens of the Mammoth Cave are not only without a trace of the optic nerve, but are also destitute of the sense of hearing. Dr. Smith at one time penetrated about four miles into the interior of the cave, and some four hundred feet below the surface of the earth. The effect upon him of the solitude and total absence of sound, he states, was very distressing, and almost insupportable, resulting in a very perceptible, although temporary, defection of hearing and aberration of mind. This explains the fact why persons lost in the cave for one, two, or three days, have always been found, when rescued, in a state of temporary insanity. The mind and special senses, deprived of their natural pabulum and stimulus, gradually become weakened, paralyzed, atrophied, and finally, as far as external manifestations are concerned, nearly, if not quite, extinct. These investigations may afford some clue to the cause of cretinism in the deep gorges of the Alps.

THE ABUSE OF PHYSICAL EXERCISE.—The *Westminster Gazette*, in the course of a declamation against too much physical exercise, sensibly observes: "Those who have gone through the severest training become in the end dull, listless, and stupid, subject to numerous diseases, and in many instances the ultimate victims of gluttony and drunkenness. Their unnatural vigor seldom lasts more than five years. It was especially remarked by the Greeks that no one who in boyhood won the prize at the Olympic games ever distinguished himself afterwards. The three years immediately preceding seventeen are years of great mental development, and nature cannot at the same time endure any severe taxing of the physical constitution. Prudence, therefore, especially at this critical period of life, must ever go hand in hand with vigor, for the evils of excess outweigh by far the evils of deficiency."

SYPHILIS CONTRACTED FROM CIGAR STUMPS.—Two cases of syphilis contracted by chewing cigar stumps picked up in the streets, have been reported in a recent number of the *Giornale Italiano delle Maladie Venere.*

Original Communications.

VESICO-VAGINAL AND RECTO-VAGINAL FISTULES.

By NATHAN BOZEMAN, M.D.,

NEW YORK.

A Vesico-Vaginal and a Recto-Vaginal Fistule in the same case; the former of Enormous Dimensions, through which the Fundus of the Bladder protruded, and made its appearance externally in the form of a large Fleshy Tumor, with both Ureters opening upon its surface—The Rectal Fistule, also of large size, complicated in the lower edge with a broad, hard, and unyielding band, closed at one operation with our Button Suture, by virtue of its protective power against the uncontrolled and poisonous Urine flowing into the Vagina all the while from the Ureters—The Vesical opening treated by transverse or horizontal obliteration of the Vagina, done at one operation with the Button Suture—First successful operation of the kind on record—Remarks.

In the great republic of science no one has the imperial right to authority, it matters not what may be the character of his investigations, further than his superior opportunities, judgment, skill, and success make him so. The bare assertion of a thing, without the necessary proof, at this advanced stage of medical science, fails to give satisfaction, and cannot be accepted by the truly scientific physician and surgeon.

A fair and honest report of cases, therefore, I have always thought was the only way of doing one's self full justice, and enabling others to arrive at satisfactory conclusions regarding the results of any particular branch of practice. So, in 1853, when I first turned my attention to the treatment of some of the injuries incident to parturition, I determined to put upon record every case that presented itself to me, whether successfully treated or not, believing that I would thereby make my experience, as far as it went, available, and thus enable other colaborers in the same field to profit by my mistakes as well as my successes; the only true way, I conceive, of subserving the great ends of science.

As to the correctness of my course, no one, I presume, will gainsay; and when it is recollected that almost every one of the injuries of which we are speaking possesses distinct peculiarities, and calls for a particular modification of treatment, the importance of the matter becomes at once strikingly manifest, and the duty of the surgeon clearly indicated.

My first case of vesico-vaginal fistule, cured by the *clamp suture* (long since abandoned by its author, and now seldom resorted to by any one, I believe), was published in the New Orleans *Medical and Surgical Journal*, for May, 1854. My second case, also cured by the *clamp suture*, was published in the *Southern Medical and Surgical Journal*, for August, 1855. My other cases, thirty-nine in number, treated with our *button suture*, were published in the Louisville (Ky.) *Review*, for May, 1856; *North American Medico-Chir. Review*, for July and November, 1857; *Edinburgh Medical Journal*, and *Glasgow Medical Journal* for Oct. 1858; *Gazette des Hôpitaux* for Jan. 4th and 6th, 1859; New Orleans *Medical and Surgical Journal*, for January, March, and May, 1860, making in all forty-one cases, and ranging through a period of about seven years.

At the date of my last report, in 1860, I can say, and with some little pride too, that my number of recorded cases exceeded that of any surgeon either in this country or Europe. Even at this writing, no other surgeon in this country has published, that I am aware of, an equal number; and it has only been exceeded in Great Britain by Mr. Isaac Baker Brown, whose entire number about equals mine, reported and unreported.

By reference to my cases, some of them will be found of the greatest interest, I think, as denoting important improvements in the treatment of certain classes of fistules, aside from the revolution that was effected almost at the very outset, by the inauguration of a *new form of suture*. I may mention, first, *the paring and suturizing of the cervix uteri*. This had been done previously, it is true, by Jobert (de Lamballe), but the precedence was unknown to me at the time of my first operation in 1855; secondly, a new and successful plan of treating *rents* of the urethra; thirdly, *the making of the uterus subservient to the closure of large fistulous openings, by hauling it down and attaching it to the anterior border of the fistule*, thus superseding the necessity of a resort to M. Jobert's dangerous and unsuccessful procedure, *d'Autoplastie par glissement ou par locomotion*, the only plan then practised in such cases by surgeons generally; fourthly, *a successful plan of disengaging or extricating the cervix uteri from the bladder when incarcerated in the latter organ, as sometimes happens, and at the same time closing the fistulous opening, thus giving the menstrual flow its natural outlet, a procedure in which I claim priority, and so far as my reading extends there are no other cases, except my own, to be found upon record, treated according to my method or otherwise;* fifthly, *transverse or horizontal obliteration of the vagina in a class of cases where the loss of tissue has been so great as utterly to preclude the possibility of closure of the fistulous opening in the usual way.*

The grounds upon which I claim priority in the latter operation will appear and be better understood from my remarks in connection with the narration of the following interesting case, whose peculiarities occasioned the adoption of the novel procedure. With this case I resume the publication of my reports, which will be continued in the RECORD until completed.

CASE XLII.—J. F., colored, æt. 19, entered my private hospital Jan. 1, 1859, laboring under the extensive and complicated injuries above stated; of medium stature, well formed, and healthy looking. About the age of sixteen was confined with her first child, at full term; labor was short and unattended with difficulty; the result being satisfactory as regarded both mother and child. Eighteen months afterwards was confined with her second child: labor lasting this time about forty-eight hours; child still-born. No instruments were used, a midwife being the attendant.

Patient thinks she did not pass any urine during labor, and believes that her suffering was greatly increased from this circumstance; says that her urine began to dribble from her as soon as labor was completed, and from that time to the present moment has never been able to pass it in the natural way. The general health to all appearances is good, far better than could have been expected under the circumstances.

Examination.—The patient, on being placed upon her knees and elbows before a strong light, was found to have a sufficiently capacious pelvis, the labia majora were thickened and excoriated, and between them protruded the fundus of the bladder, in the form of a large fleshy tumor, as large as a medium-sized orange, with both ureters plainly visible upon its surface. Gentle pressure with the ends of the fingers upwards and backwards, upon this extruded portion of the bladder, carried the fundus through the immense chasm in the anterior wall of the vagina to its normal position. The introduction now of the lever speculum brought fully

into view a fistulous opening, with *metes* and *bounds* truly appalling. In the sloughing process I found that nearly all of the infravaginal portion of the cervix uteri, the basfond and trigone of the bladder, and nearly one-half of the urethra had been carried away, thus presenting an example of a fistule belonging to both my *fourth* and *fifth classes*,* which I had never observed before.

The borders of this opening, as well as the stump of the cervix uteri, had the appearance of being healthy, there being no abrasions, as are commonly seen in injuries of this nature far less serious. A striking feature, however, was their immobility; no movement of its sides or depression of the uterus could be effected, thus precluding the possibility of any compensation for loss of tissue by hauling the uterus down, as I had always been able to do before in the largest sized fistulous openings.† Another feature of the anterior border is worthy of note—viz., the partial exposure of the pubic arch; the bones could be traced with the finger half or three-quarters of an inch on either side of the symphysis pubis. I next had the patient to turn upon her back, in order to explore the posterior wall of the vagina, having already perceived indications of a *recto-vaginal fistule*. The introduction of the speculum at once disclosed the situation and nature of this additional, and, I may say, very grave and serious injury, complicating as it did the one which we have just described of such formidable proportions. It was situated about two and a-half inches from the anus, and was oval in shape, with its long axis extending directly across the *recto-vaginal septum*. Its lower border was involved in a broad, hard, and somewhat unyielding band, which extended entirely across the posterior wall of the vagina. This band I found to influence very materially the mobility of the edges of the fistule, and there was a doubt in my mind at the time as to whether their approximation could be effected, even with the best course of preparatory treatment that could be instituted.

Treatment.—Here I must be allowed to quote my own remarks from the New Orleans *Medical and Surgical Journal*, for January, 1860. Upon resuming the publication of my cases in that journal, these remarks were called forth by the peculiarities of this particular case, and the treatment that was adopted for its successful management, May, 1859. I am thus particular in stating the precise dates of treatment and publication of remarks, as the question of priority of operation will be discussed hereafter:

"Several of the cases that I am now about to report are of unusual interest; one, perhaps, the most remarkable on record. This was a case of both vesico-vaginal and recto-vaginal fistules, and from its peculiarities occasioned the inauguration of a new and successful plan of treatment never before adopted, that I am aware of, and one to be regarded of the greatest practical utility.

"The unyielding nature of the posterior septum could not be overcome by any plan of treatment. This, therefore, left us with no other alternative than the obturation of the vagina at the vulva, according to the method of Vidal (de Cassis). In addition, now, to the ordinary objections to the above procedure, there was one in the present instance, that at first appeared insurmountable; namely, the existence of the recto-vaginal fistule. With this remaining, not only the urine and catamenia, but the fæces, would have been turned into one common receptacle, with no other outlet than the urethra. For the latter to become dissolved in the other two excretions, and be discharged with them, would have been next to impossible. M. Vidal's operation, therefore, was out of the question, unless the recto-vaginal opening could first be closed; and to the success of this there appeared one very great obstacle, namely, the uncontrolled urine. This, in almost any position of the patient, would necessarily come more or less in contact with the raw edges of the fistule when brought together, and by its irritating effect have prevented their union. Relying, however, upon the protective power of our button, as shown on former occasions in the management of double and triple vesico-vaginal fistules, I resolved to hazard an attempt at least to place our patient in a condition for obturation of the vagina, which, however partial the relief promised, seemed to be called for under the circumstances. I say partial relief, because it is well known that closure of the vagina, as directed by M. Vidal, leaves the patient with no control over the urine, to say nothing of the ill consequences arising from the more or less stagnation of this fluid and the catamenia at the lower part of the vagina. To prevent the latter result, therefore, it required that these excretions should always be freely and completely discharged, whether involuntarily or not. This, in my judgment, could be effected in no other way than by *attaching the posterior to the anterior wall of the vagina just below the vesical extremity of the urethra, thus placing our line of cicatrization horizontally and far above the perpendicular one of M. Vidal, just within the meatus urinarius*. Therefore, after closing the recto-vaginal opening, if possible, I determined to put into practice this new procedure. Accordingly, I went to work, and to my great astonishment the rectal opening was closed at our first trial. It remained now for me to see what could be realized by the procedure above proposed."

The operation consisted simply in paring off the mucous membrane across the anterior wall of the vagina up to the very brink, so to speak, of the chasm already described. In a similar manner the mucous membrane was pared off around and across the posterior vaginal wall, just opposite, and to a corresponding extent. The denuded surface all around averaged in width half to three-quarters of an inch.

This stage of the operation being completed, eight silver-wire sutures were next introduced and adjusted in the usual manner, which brought the two raw surfaces of the opposing walls of the vagina in perfect apposition. A *button* then of the ordinary shape, one inch and three-quarters in length, with holes to correspond to the number of sutures, was next slid down upon the approximated parts, and then secured by compressing a perforated shot upon the two ends of each wire. A catheter was now lodged in the urethra, and the patient placed in bed. In the after treatment no other attention was called for than that required in an ordinary case of vesico-vaginal fistule. Suture apparatus removed on the ninth day.

"Suffice it to say, our first operation was attended with entire success, and our patient, contrary to the most sanguine hope, had almost complete control over her urine. I say almost complete, because she retains and passes it at will, dribbling only taking place from the urethra occasionally when she goes too long without emptying the bladder. She keeps perfectly dry at night, not requiring to get up at all, and during the day, when walking about, she can sometimes go three or four hours without any dribbling.

"When I performed this operation, I did not for a moment suppose that our patient would regain, to any extent, the power of controlling her urine, if ever so successful. The most that I hoped for was a mechanical

* See *North American Med. Chir. Review* for July, 1857.
† *Op. cit.*

obstruction to its flow while the patient was in the recumbent posture, thus enabling her to lie dry at night. The result, however, has proved most conclusively that the vagina, thus occluded, secures to the patient the power of retaining and passing her urine at will, as though the fistulous opening itself were closed.

"This operation, therefore, cannot be regarded otherwise than as a great triumph. It enables us now to manage a class of cases, if not as satisfactorily as we could desire, certainly upon scientific principles, and with results never heretofore attained, as far as my information extends. Vidal's operation, however successfully performed, must, from the very nature of things, always be attended with an involuntary flow of urine upon leaving the recumbent posture, and therewith a downward pressure or unpleasant feeling at the lower extremity of the vagina, caused by the accumulation of urine and the catamenia constantly going on there."

Remarks.—The result in this case, as regards both the recto-vaginal fistule and the *transverse or horizontal obliteration of the vagina*, must strike every one, under the circumstances, as being satisfactory in the highest degree. Something over eight years having now elapsed since this operation was done, I have only to say my views have undergone no change, as to the importance of the procedure and its superior advantages over M. Vidal's method.

Recent and further examination into the literature of the subject satisfies me that my claims to priority in the operation of which we are speaking were just, at the time I first called the attention of the profession to it in the journal already referred to. Neither in this country, France, Great Britain, nor Ireland, had there been at the period named a successful operation of the kind; and even now, the records of the profession in the countries named, so far as my reading extends, do not afford another authenticated example.

In Germany, it is true, Prof. Simon, of Rostock, a few months before I performed my operation, proposed precisely the same procedure,* *cross obliteration of the vagina* (*queren obliteration der scheide*), and had actually performed the operation twice, though without any success. We have, therefore, no proof of his having ever effected a cure by his procedure prior to the date of my paper. But when we know the kind of cases in which Prof. Simon first proposed his operation, there will not be found such a willingness, I imagine, to award him the credit he might otherwise have been entitled to. He tells us that the case which suggested this novel procedure to him was one in which the vagina was almost in a normal state, and the fistulous opening so small as only to admit the end of the finger, *but it was deeply situated in the vagina and difficult to approach.* These were the circumstances, after several attempts to close the small fistule, we are told, which called forth the above expedient, and which fortunately proved equally unsuccessful. I say fortunately, because it was truly so to both patient and reputation of surgeon, for the latter tells us afterwards he succeeded in closing the same fistule and discharged the patient cured, a result to her infinitely preferable to that of an obliterated vagina, and certainly more in accordance with correct principles of surgery, all must admit. As appears from the date of Simon's article quoted, he did not publish his views until two years after mine appeared, but he makes no mention whatever of my case or operation. I should be disposed to attribute this oversight or neglect to the fact of his having not seen my papers, but the palpable injustice is made manifest by his resort to my plan of suture, and in the very case too upon which he first tried *transverse obliteration* of the vagina, and failed.

I will defer saying more at the present time in connection with this important operation, as I hope to be able soon to present my views upon it in a different form, and with suitable illustrations.

* Ueber die Operation der Blasen-Scheidenfistein durch die Blutege Naht. 1862.

ACUTE INFLAMMATION OF PSOAS MAGNUS MUSCLE.

BY J. W. GROSVENOR, M.D.,

PROVIDENCE, R. I.

ACUTE inflammation of the psoas magnus muscle is a very rare disease. In searching medical literature I find only a single case reported in detail, and that by Dr. C. W. Parsons, of this city, in the Boston *Medical and Surgical Journal* of September 10, 1851. A case is mentioned by Prof. Gross in the 1866 edition of his surgery. On page 594, he says, "An instance has been reported of a young man who died from rupture of the psoas muscle, death having been preceded by severe inflammation and infiltration of pus."

In a letter to Dr. Anthony, of this city, Prof. Gross regrets his inability to refer to the particular case. Prof. Willard Parker informs me by letter that he has the notes of two unpublished cases which have occurred in his practice. I hope we may soon see them in print.

The following case has lately come under my observation.

Lemuel Grosvenor Perry, a student, nineteen years of age, strong and healthy from birth, while playing ball, on June 27, 1867, felt something "give way" in his right side.

Soon after returning home on the same day, he was taken sick with vomiting and quite a sharp pain in the right lumbar region. Tongue was slightly furred, bowels constipated, pulse full and about ninety per minute.

A cathartic of magnesia in combination with charcoal acted promptly, by which the pain was considerably relieved and the vomiting entirely. On the morning of June 29th, patient had quite a severe chill. For the four or five days following there was but little change in the symptoms—pulse fair, and about eighty per minute, tongue slightly brown and moist, stomach uncomfortable, tendency to diarrhœa, the pain in the right lumbar region continuing, though not severe. July 4th, a swelling and hardness were observed over the seat of the pain. It was circumscribed, and covered a space of about four square inches, its centre being on a vertical level with the anterior superior spinous process of the ilium. For two or three days it became a little more prominent, and then remained *in statu quo.*

Patient found urination difficult without standing. He could not fully extend his right leg, kept the right thigh flexed on the abdomen, and rotated outwards, moved from side to side in bed with difficulty and pain; when on his feet assumed a stooping posture, with the body inclined towards the right side. Abdomen not swollen, and not tender on pressure, except in right lumbar and right iliac regions. From about the 4th to the 12th, patient was comfortably sick, was able to get up without assistance every day, his pulse fair, the general symptoms being the same as during the few days previous to the appearance of the swelling. At 3 A.M. of the 12th, he was seized with a severe pain and excessive vomiting of a greenish-looking material; cold, clammy perspiration followed, pulse became very rapid and feeble. Vomiting continued with slight abatement till death at 6½ o'clock P.M. of the same day.

Treatment previous to the sinking stage, on July 12th, consisted of a cathartic at the outset of the disease, as already mentioned, injections of starch and laudanum to control the diarrhœa, anodynes sufficient to relieve pain and procure rest and sleep at night, animal broths and some fruits, occasionally brandy and water. The tumor was painted with tincture iodine for several days, and leeches applied to it on the 11th. In the stage of collapse treatment consisted in morphia injected hypodermically, and iced champagne, to which were added a few drops of chloroform. During his sickness the patient, who was under the medical care of his father Dr. Perry, was seen by Drs. Peckham and Parsons, of the city, and Dr. Clapp, of Pawtucket.

Autopsy by Dr. Mason, seventy-two hours after death. Greater omentum slightly adherent to small intestines, which were considerably congested. Lower part of ascending colon and appendix vermiformis adherent to abdominal wall. A few fibres of psoas magnus muscle were rough and broken down, and the muscle itself dissected up along its posterior surface, and the peritoneum separated from its anterior surface. The anterior crural nerve running along the outer border of the muscle was separated from all attachments for a distance of six inches. About three pints of purulent fluid in peritoneal cavity. The rupture of the peritoneum was apparently between the stomach and liver. Right kidney healthy. No diseased bone discovered.

Undoubtedly inflammation commenced at that part of the psoas magnus muscle where the fibres were broken down, an abscess followed, and pus as it was formed burrowed under the muscle, dissected up the peritoneum, and finally burst into the peritoneal cavity on the morning of July 12th, at the time when the alarming change in the symptoms occurred.

I have seen no account of this disease in the English language. In Copland's Medical Dictionary occurs an article on inflammation and suppuration of the psoas muscles. The author mentions psoitis as one of its synonymes, but he evidently refers to psoas abscess, which is a *chronic*, not an *acute* disease. The only article on this subject which I have seen is in the *Dictionnaire de Medicine*, vol. xxvi., under the heading Psoite. The rarity of the disease, and the meagre amount of literature upon it, may justify me in presenting a resumé of this article.

Causes of Psoitis.—Falls, blows on lumbar region and pelvis, violent movement of body backwards and forwards on lower extremities; raising heavy weights; very severe exercise. Ferrus, the author of the article, thinks rheumatism has a great influence on the development of the disease.

Symptoms.—Pain in lumbar region, which soon extends to groin and thigh—usually intolerable, rarely almost nothing. Extension and flexion of thigh greatly increases the pain. Walking difficult or impossible. If patient walks trunk is strongly inclined forwards. Engorgement of inguinal glands. As disease progresses pain becomes severer, and lower extremity of affected side is constantly flexed and slightly turned outwards. An attempt at extension or rotation gives excessive pain. This position of the limb is ordinarily the most characteristic sign of psoitis. Sometimes there is numbness in the limb. Fever declares itself, digestive organs become deranged; sometimes nausea and vomiting occur, often diarrhœa, rarely constipation; urine is sometimes purulent, sometimes colored with blood. At last in the groin or lumbar region appears a tumor more or less extensive, fluctuating, not changing color of skin, not painful on pressure, drawing back into interior of abdomen. In this tumor, whether it opens spontaneously or is opened by an instrument, is found more or less pus. Hectic fever follows, pulse becomes small and frequent; a cough appears, colliquative diarrhœa supervenes, and the patient dies of marasmus.

Pathological Anatomy.—The muscle is found in three conditions. First, it is entirely preserved, but softened, in color like the lees of wine, infiltrated with black blood, and easily torn. Secondly, vestiges of the muscle remain, of the consistency of pulp, blackish in color, and of a disagreeable odor. Thirdly, the muscle is completely destroyed by suppuration.

The secretion is not pure pus, but a mixture of pus and muscular fibres not entirely broken down. Usually suppuration extends outwards towards the surface, but Ettmaller and Withmore have each reported a case in which the purulent matter found its way into the intestine and appeared in the evacuations. These two patients died, and the autopsies revealed a communication between the abscess and colon in both cases. Sometimes the secretion follows the psoas and iliacus muscles as far as their insertion into the lesser trochanter, and infiltrates the muscles surrounding the coxo-femoral articulation.

Diagnosis.—The symptom which may be considered pathognomonic is flexion of the lower extremity upon the trunk in the direction of the fibres of the psoas muscle.

This sign, taken in connection with the acute pain caused by rotating the limb, will enable us to make out a diagnosis in a large majority of cases. Sometimes a diagnosis is very difficult. From abscess due to a change in lumbar vertebræ it may be distinguished by the rapidity of its course, by absence of deformity in vertebral column, by the impossibility of extending the leg and of easily executing the movement of rotation. Nephritis, although resembling psoitis in the seat of the pain, differs from it in not preventing the movements of extension and rotation of the limb. In hernia the absence of fluctuation in the tumor, digestive troubles, and absence of lumbar pain, exclude the existence of psoitis. Sometimes there is great difficulty in diagnosticating between coxalgia and psoitis. In the latter as in the former, the pain extends along the thigh and sometimes as far as the knee, and also there is sometimes the same difficulty of rotation in one as in the other. Still, the principal seat of the pain at the outset of the disease being in the lumbar region in psoitis, and in coxalgia in the external iliac fossa, will usually prevent any mistake. (From abscess of the appendix vermiformis and from iliac abscess I think psoitis may be distinguished by the peculiar position of the limb in the latter, viz. flexed upon the abdomen and rotated outwards.)

Prognosis.—Psoitis is a very grave disease. Dr. Kyll thinks the prognosis very favorable, all his five patients having recovered, and yet he admits that he is not quite sure whether the seat of the disease was in the psoas muscle, the lumbar vertebræ, or the pelvic cellular tissue. Psoitis does sometimes terminate in recovery, as is shown by a case reported by La Motte. Fluctuation was felt deeply along the vertebræ and loins between the last rib and ilium. A large incision was made, and six pounds of pus extracted. After five months the patient recovered. There was some doubt, however, as to the nature of the disease. (Prof. Willard Parker informs me that the two cases which have come under his observation recovered.) In the collections of pus which form in the pelvic cavity the bursting of the abscess into the intestines is considered favorable, but in psoitis such an event is considered unfavorable, as is shown by the two cases already mentioned.

Treatment.—As soon as the patient complains of pain along the track of the psoas muscle, and other circumstances enable us to predict inflammation, general bleeding is recommended, repeated applications of leeches

and cups to the loins and groin, fomentations, frictions with mercury, ammonia, iodine, etc. Finally, blisters and cauteries may be employed. If suppuration takes place, the painful parts should be covered with warm poultices; and constipation should be relieved by a purgative or laxative. If the abscess points at the surface, it should be opened.

CASE OF POISONING BY ALCOHOLIC EXTRACT OF BELLADONNA.

By H. A. DUBOIS, M.D.,

ASSISTANT SURGEON, U.S.A.

As the following case presents several points of interest, I transmit it with but few comments:

December 28, 1866, feeling indisposed, I ordered for myself: Sulph. quin., grs. v.; ext. coloc. co., grs. x.; pil. mass. hyd., v.; M. Ft. pil. No. iv.

I received the four pills, two of which I at once took, and soon after retired (about eleven P.M). I slept but little, but was not very restive, and did not observe anything peculiar in my sensations until near eight A.M. the following morning, when, on putting my foot to the floor, I came near losing my balance, and staggered for some distance across the room, unable to support myself steadily, or regulate the movements of my legs. Dressing with much difficulty, I managed to reach the surgery, where, seating myself, I commenced prescribing for the sick. I now, for the first time, found that I was unable to read the names on the sick report, the page appearing perfectly blank. Up to this time I had not been able to control my thoughts. On rising, I remember that I had a faint idea that something was wrong, but was unable to say what; the acts in putting on my clothes were performed nearly involuntarily, the prominent idea being the necessity I was under of being punctual at my post at sick call. Not seeing any names on the sick report, I asked the steward the reason, and then discovered that I could not control the movements of my tongue. I managed, however, to make myself understood, and was informed that the names were there. I remember that then, by a strong impulse, I collected my thoughts to endeavor to ascertain the cause of my disability. The first thought which presented itself was that I was drunk, but this I rejected, as I could not remember having drunk any intoxicating liquor the preceding day. Next, I ran over my actions the evening before, and I recalled the two pills I had taken, recollected their composition with difficulty, and the thought then struck me that as the extract of colocynth and extract of belladonna were both put up in pots much alike, one had been mistaken for the other. I remember that I recalled the amount that I had probably taken, and determined that I would prescribe for the sick, if I could neither see, speak distinctly, nor stand steadily, before I retired to my room. I ordered the steward to call the names out, and when the first man came up I could see his outline, but could not recognize his features. I, however, remembered his name and what should be the matter with him, and having his last prescription read out, I continued it, afraid to trust myself in prescribing. In this way, with few changes, and then careful to use the simplest of medicines, I saw, or rather did not see, some thirty sick, for each of whom I prescribed, or continued his former prescription.

I then returned to my room with a brain whirling, a dull, heavy pain in the back of the head, and my mind wandering from time to time. I recollect distinctly trying to collect my thoughts, and using the utmost exertions of my will to keep them fixed, so as to try to remember the smallest fatal dose of the extract of belladonna, and to recall all the symptoms of poisoning from that drug, and their proper treatment. I came to the conclusion that I would treat myself on general principles. I had some strong coffee brought and put before me, and drank cupful after cupful. I sent for whiskey, and mixing it with the coffee, I continued its use, taking also, during the day, several half-grain pills of morphiæ sulph.

This treatment relieved the giddiness. I found my mind ceased to wander, and though a vague feeling—a feeling of vacuity—of a lack of something, still continued, together with a severe pain in the back of the head whenever I tried to think, I felt better. I now tried to examine my eyes in a glass, but could only see a general outline. However, by going across to the other side of the room and looking at the glass, I managed to discover that my pupils had expanded so that I could see no iris. As I now look back to this period, everything—my thoughts and actions—all seem vague and misty; though I remember them, and that distinctly, still the thoughts seemed to have formed themselves under the power of a strong effort of the will, and that the least relaxed, the thought would escape. So too, with my actions. In walking, I can remember that on fixing one foot on the ground, it required an effort of the will to raise the other, and much judgment in so placing it that the body's centre of gravity was preserved. My arms and legs—but the latter not to the same extent—felt numb and cold to my touch. With great difficulty I held anything in my hands. By noon, or four hours since I first noticed the effects of the poison, I was able to visit and prescribe for some twenty patients in hospital, but returned greatly exhausted This state continued all the afternoon and evening, and I passed a sleepless night; my mind wandering, and vague and misty visions presenting themselves. For two days my vision continued much impaired, and then it gradually became normal as the pupils resumed their usual size.

While my vision was most impaired, I noticed objects nearly as well as ever a mile or two out on the prairie, though if I looked attentively, the effort became exceedingly painful. The action of the brain slowly became normal. Exertion of any kind—even the reading of the simplest book—caused intense fatigue, and a dull heavy pain in the back of the head. These symptoms, together with great lassitude, continued for between two and three weeks. There are a few symptoms that I have neglected to mention. Colicky pains, and dryness of mouth and throat presented themselves on the second day. The dejections for several days were dark colored, and extremely offensive, and the urine was voided frequently and in large quantities. Some days after these symptoms, I noticed on my hand a large red blotch, which disappeared on pressure, and which in the course of a week faded, leaving the skin rough. For two months I felt lassitude, and but little mental exertion was required to bring back the peculiar feeling in the head.

I have described this case with minuteness, as its chief point of interest seems to me to reside in the control the will appears to have had over the cerebrum, constantly bringing the mind under control, and holding it to its work; and in the remembrance of things, and their appearance, seen with a brain and through optic nerves poisoned with belladonna.

In conclusion, I will only add that the amount of poison taken was five grains. The preparation used was Squibb's alc. ext., and, as I had supposed, it had been used for the ext. coloc. co. by the soldier whom I had been compelled to use as a steward.

Original Lectures.

LECTURES UPON THE PHYSICAL EXPLORATION OF THE ABDOMEN.

DELIVERED IN THE PRELIMINARY COURSE AT THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF NEW YORK.

By ALFRED L. LOOMIS, M.D.,

PROFESSOR OF INSTITUTES AND PRACTICE OF MEDICINE.

Lecture II.

PHYSICAL SIGNS OF DISEASED CONDITIONS OF THE LIVER AND SPLEEN.

Gentlemen—I will endeavor this morning to detail to you the physical signs by which we determine the changes that take place in the liver and spleen during the progress of disease. I will commence with the LIVER: Our diagnosis in any case of hepatic disease rests mainly on the size, form, and position of the liver, as determined by percussion and palpation. The first step then in studying the physical signs indicative of disease of this organ is to become familiar with its normal boundaries. In its healthy state, the right lobe of the liver occupies the right hypochondrium, lying completely in the hollow formed by the diaphragm, rarely descending below the free border of the ribs, or extending upwards above the fifth intercostal space; the left lobe reaches across the median line to the space below the ensiform cartilage.

The upper boundary of the organ is determined by percussing with moderate force from the right nipple downwards until the flatness of the percussion sound indicates that a solid organ has been reached; draw a line at this point. Then percuss downwards from the axilla, and from a point a little to the right of the median line in front, in the same manner, until the same change occurs in the percussion sound; a line drawn through the points which mark these changes in the percussion sound, determines the upper boundary of the liver, and it will be found generally to correspond to the base of the ensiform cartilage on the median line in front; to the fifth intercostal space on the line of the right nipple; to the seventh rib in the axillary region, and to the ninth rib in the dorsal region. The lower boundary of the organ is determined by percussing downwards from the line of flatness already determined, and noting the points where the tympanitic sound of the stomach and large intestine occurs, which will generally be found to correspond anteriorly with the free border of the ribs, and to a point three inches below the ensiform cartilage on the median line; laterally in the axillary region to the tenth intercostal space; and posteriorly in the dorsal region to the twelfth rib. The flatness of the left lobe usually reaches two inches to the left of the median line. The whole margin of the liver (except where it comes in contact with the apex of the heart through the medium of the diaphragm) may thus be determined and marked out on the surface. The vertical measurements will be found very nearly as follows: three inches on the right of the median line in front, four inches on a line with the right nipple, four and one-half inches in the axillary region, and four inches posteriorly in the dorsal region. The smooth edge of the lower margin of the liver in health (especially in thin subjects) can be distinctly felt underneath the free border of the ribs.

The healthy liver in its normal position evidently influences very little the percussion sound over the lower half of the abdomen, which (as has already been stated), when the organs there situated are normal and empty, yields tympanitic resonance from immediately below the margin of the ribs to the pubes; if, therefore, the percussion sound is dull over any portion of this space, and the dulness is uninterrupted to the margin of the ribs on the right side, we have good reason for believing that the liver is the organ diseased.

The *normal boundaries* of the liver already defined may be greatly altered without any abnormal change occurring in the organ itself. These normal changes, unless remembered, may lead to errors in diagnosis. Thus congenital malformations may give rise to an increase in the area of hepatic dulness; an accurate history of the patient, however, will keep us from error in such cases.

In examination of children, it should also be remembered that the liver is proportionally larger than in adults.

The practice of tight-lacing may cause displacements and malformation of the liver, and thus give rise to apparent hepatic enlargements. The marks which this practice leaves on the chest wall will be sufficient to attract our attention, and so prevent mistake.

Diseases of the thoracic organs, and abnormal conditions of the other abdominal viscera, sometimes cause displacement of the liver, simulating very closely hepatic enlargement; these we will consider under the head of *differential diagnosis* of the diseases of the liver.

Variations in the size of the liver in hepatic diseases.—Variations in the size of the liver occur in almost every disease to which it is subject. It is *increased* in size in *fatty liver*, in *waxy liver*, in *hydatid tumor*, in *abscess of liver*, in *congestion*, in *acute hepatitis*, in *obstruction of the bile ducts*, and in *cancer*.

It is *diminished* in size in *cirrhosis*, and in *acute atrophy*.

Enlargements of the liver were divided by Dr. Bright into smooth and irregular. Dr. Murchesson has divided them into painless and painful enlargements. Both of these divisions, it seems to me, have their objections, and in giving the physical signs of the various diseases accompanied by enlargement of the organ, it is hardly practicable to adopt either of them exclusively.

Fatty Liver.—In fatty degeneration of the liver the organ is uniformly enlarged; there are no circumscribed bulgings; its normal shape is unaltered; there is no expansion of the lower ribs, it *never* gives rise to ascites, and it is not attended by any visible enlargement of the superficial veins. In palpation below the margin of the ribs on the right side, and in the epigastrium, a soft cushion-like enlargement is readily detected, extending not unfrequently as low as the umbilicus; its outer surface is smooth, and its lower margin is rounded and not well defined; it is never *tender* on pressure. On percussion there is flatness over the surface of the abdomen, corresponding to the enlargement.

Waxy Liver.—In waxy or amyloid degeneration, the organ undergoes greater enlargement than in fatty degeneration; it often becomes so large as to fill the whole abdominal cavity; its growth is slow, usually extending over a period of two or three years. The enlargement is uniform, and the area of hepatic dulness is consequently increased on percussion in every direction, more however in front than behind. There is often on inspection a visible tumor below the margin of the ribs, but there is no bulging of the ribs themselves. *On palpation*, the portion of the organ below the ribs is dense, firm, and resistant, the outer surface is smooth, the lower margin is sharp and well defined. Pain and tenderness are rarely present, so that the portion of the

organ below the ribs (as in fatty degeneration) can be manipulated without giving the patient any inconvenience. When excessive, it is almost always accompanied by ascites.

Hydatid Tumor of the Liver.—Hydatid cysts, when small or deep-seated, cannot be detected by physical examination; but large and superficially seated hydatid cysts are recognized by abnormal increase in the area of hepatic dulness, the outline of the dulness being irregular, and by the globular form of the enlargement on the surface of the organ. Sometimes these cysts are so large as to cause the organ to fill a large portion of the abdominal and right pleural cavity; the natural form of the organ is greatly altered, the enlargement taking place more in one direction than in another. Sometimes percussion over a large hydatid cyst will give rise to a characteristic vibration (known as hydatid fremitus); this vibration is produced by the collision of the smaller cysts that are contained in a large one. A hydatid liver encroaching on the thoracic space gives rise to flatness on percussion, and absence of respiratory sound, from the base of the chest upwards as far as the tumor extends, the upper boundary of the flatness being arched. It is distinguished from pleuritic effusion in that a change in the position of the body does not change the line of percussion dulness. On palpation sometimes the enlarged portion below the ribs has an elastic or even fluctuating feel, and if a large cyst be near the surface it may give rise to a sense of fluctuation; the surface over these enlargements is smooth, and the organ is not *tender* on pressure, and its growth is slow.

Abscess of the Liver.—When hepatic abscesses exist, from whatever cause, it depends entirely upon their situation, whether an external tumor is produced or not; if the abscess occupies the posterior portion of the right lobe, the liver is pushed down so that its margin is perceptible below the free border of the ribs, and the flatness on the right side posteriorly extends higher than natural. When an abscess is superficial and is pointing externally, a distinct tumor is felt below the ribs; the situation of the tumor varies according as the right or left lobe is affected, and there is always more or less bulging of the ribs if the right lobe is affected. A tumor arising from such a cause is easily traced as connected with the liver, of which it evidently forms a part, the flatness on percussion being continuous. Sometimes the organ is enormously enlarged, its free border extending below the umbilicus, the surface of the enlargement being smooth, and *excessively tender* on pressure. The sensation to the examiner on making light pressure will be soft and fluctuating, or that of elastic tenderness. In some rare instances, abscesses produce an uneven or lobulated condition of the surface; under such circumstances, it may be mistaken for cancer, unless the rational symptoms and history of the case be included in the elements of diagnosis. The enlargement goes on rapidly; with a correct history of the case the diagnosis is easily made.

Congestion of the Liver.—The most simple form of hepatic enlargement is that which results from congestion. When the liver is thus loaded with blood, a slight fulness is perceptible on the right side. On palpation the space immediately below the ribs is occupied by a smooth, hard, resisting enlargement, corresponding to the natural shape of the liver, which is not usually tender to pressure, and there is no well defined tumor. On percussion a flat sound is elicited an inch or two below the margin of ribs on the right side.

Obstruction of the Bile-ducts.—A similar enlargement of the liver to the one just noticed occurs when, from any cause, there is obstruction in the biliary ducts, and an accumulation of bile takes place in the liver. Sometimes when this occurs, in addition to the general enlargement detected by the slight uniform increase in the normal area of hepatic dulness, a globular projection is detected at a point corresponding to the transverse fissure of the liver, with the elastic feel of deep-seated fluid; this tumor is the distended gall-bladder.

Acute Hepatitis.—The physical signs of acute hepatitis do not differ materially from those of simple congestion, except in the excessive pain that exists on pressure over that portion of the organ which descends below the ribs.

Cancer of the Liver.—In most cases of cancer, the diagnosis is easily made by the physical signs.

On percussion, the area of the hepatic dulness is always increased, sometimes extremely so; the organ is found to occupy the greater portion of the epigastrium, extending beyond the median line to the left hypochondrium (pushing the diaphragm upwards), and often descending below the ribs to the crest of the ilium.

On palpation, irregular nodules of various sizes are distinctly felt through the abdominal walls, projecting from the surface of that portion of the enlarged organ which is below the free border of the ribs; these prominences are usually harder than the surrounding hepatic tissue, and there is more or less tenderness on pressure over them. Cancer of the liver may or may not be accompanied by ascites. Occasionally the surface of the liver in cancer is perfectly smooth, and in such cases you will be unable to detect the disease by the physical signs.

Diminution in the Size of the Liver.—The liver is diminished in size in cirrhosis, and in acute atrophy.

Cirrhosis of the Liver.—In fully developed cases of cirrhosis of the liver, the organ is always diminished in size, and there is more or less abdominal dropsy. The only evidence of this disease furnished by inspection, is a visible enlargement of the superficial veins.

Percussion.—The area of the normal hepatic flatness is diminished, and its limits are determined as follows: If the abdominal cavity is distended with dropsical accumulation, the patient should be placed partly on the left side, so that the fluid will gravitate from the hepatic region; the percussion flatness then, instead of extending to the free border of the ribs, will often give place to tympanitic resonance an inch or more above their free margin, and instead, also, of extending across the median line into the left hypochondrium, will rarely reach that line, while the vertical measurement of hepatic dulness, on a line with the right nipple, often does not exceed two and a half inches.

Palpation.—By firm pressure with the ends of the fingers upwards, little nodules will often be felt on the under surface of the organ. Sometimes, when the distension of the abdomen from the dropsical accumulation has been very great, we can get no information by palpation until after the performance of paracentesis.

Atrophy of the Liver.—The only physical sign of atrophy of the liver is progressive diminution in the size of the organ as ascertained by percussion, its surface remaining smooth, the diminution not being accompanied with ascites.

Differential Diagnosis of Diseases of the Liver.—The sources which may lead to error in the conclusion that the liver is the seat of disease when it is not, are—first, accumulations in the ascending and transverse colon; diseases with enlargement of the right kidney; diseases of the stomach; displacement of the liver by disease in the right side of the chest; enlargement of the spleen; tumors of the omentum, and ovarian tumors.

Fæcal Accumulations.—To distinguish these accumulations from enlargement of the liver by physical ex-

amination is always difficult and sometimes impossible; they give rise to a distinct tumor below the border of the ribs, which, by percussion and palpation, seems to be continuous and connected with the liver. The differential diagnosis can only be made after making trial of remedies which, by acting freely on the bowels, remove the accumulation and cause the disappearance of the supposed hepatic enlargement.

Disease of the Right Kidney.—The right kidney sometimes enlarges in such a manner as to present itself as a tumor, extending from the under surface of the right lobe of the liver. If it has attained considerable size, it may therefore seem to be continuous with the liver as a growth from its substance. It may be distinguished from the liver by carefully examining its relation to the ribs; as the patient lies on his back, the enlargement, instead of passing up under the ribs, slips down, so as to allow the finger to pass vertically between the tumor and ribs.

Disease of the Stomach.—The only disease of the stomach which we are likely to confound with enlargement of the liver is cancer. It can, however, usually be readily distinguished from it by the tympanitic quality of the percussion sound over the cancerous mass, and by the mobility of the supposed enlargement.

Displacements of the liver downwards from extensive pleuritic effusion and from pneumothorax are recognized by the presence of the physical signs which indicate these thoracic diseases.

Enlargement of the spleen, and *ovarian tumors*, are distinguished from enlargements of the liver by the shape of the tumor, and by the continuous and increasing flatness of the percussion sound as we pass towards the normal position of these organs.

Spleen.—The spleen, from the obscurity which involves its natural function, so that its affections usually give rise to but negative general symptoms, and from its comparatively isolated situation, often presents greater difficulties in the diagnosis of its morbid conditions than is the case with any other abdominal organ. In health this organ occupies the upper portion of the left hypochondriac region, its lower border touches the left kidney, while its convex surface occupies the concavity of the diaphragm. It is bounded superficially, above, by the lower border of the ninth rib, anteriorly by the stomach and colon, and inferiorly by the free margin of the ribs. It is about four inches long and three inches wide. In its healthy condition, inspection and palpation furnish only negative results.

Percussion.—To determine the boundaries of the spleen by percussion, it is necessary that the patient should lie on the right side. Its anterior border is readily determined by the tympanitic resonance of the stomach and intestines. Posteriorly, where the organ comes in contact with the kidney, it is difficult and often impossible to determine its boundary. Its superior border corresponds to the line which marks the change from flatness to pulmonary resonance. The inferior is known by the tympanitic resonance of the intestine.

In disease the spleen may be increased or diminished in size. We are rarely, if ever, able to recognize atrophy of the spleen during life. In most cases of splenic disease there is neither pain nor tenderness. The only reliable physical signs of disease of the organ are connected with its enlargements. The tumor produced by the enlargement of the organ can scarcely be overlooked. Its characteristics are a smooth, oblong, solid heap, felt immediately beneath the integuments, extending from under the ribs on the left side, a little behind the origin of the cartilages, often advancing to the median line in one direction, and descending to the crest of the ilium in the other, filling the left lumbar region at its upper part. This tumor is usually movable, rounded at its upper portion, and presenting an edge more or less sharp in front, where it is often notched and fissured. According to Dr. Bright, the principal tumors which may be mistaken for an enlarged spleen are—chronic abscess of the integuments, cancer of the stomach, enlargement of the left lobe of the liver, diseased omentum, fæcal accumulation in the colon, disease of the left kidney, and ovarian disease.

Chronic abscess of the integument sometimes occurs precisely in the situation of an enlarged spleen, but it is easily distinguishable from it by the superficial character of the swelling, and by its being too soft to belong to an internal viscus.

Cancerous deposit in the cardiac extremity of the stomach sometimes gives rise to a tumor which, from its being deeper than the abdominal walls, and descending from the margin of the ribs, might be mistaken for an enlarged spleen. One of the best marks will be found in the sound elicited by forcible percussion, which, when the stomach is diseased, has more or less of a tympanitic resonance, while the tumor is harder to the feel than an enlarged spleen.

Enlarged left lobe of the liver is easily distinguished from enlarged spleen, for the margin of the tumor can be traced running towards the right, and not towards the left as is the case with enlarged spleen.

Cancerous and tuberculous enlargements of the omentum are distinguished from an enlarged spleen by the fact that they extend across the abdomen and cannot be traced backwards; they do not descend from beneath the ribs, and are rough, hard, and uneven.

Fæcal accumulation in the intestine is a source of very great difficulty in this diagnosis, for when it takes place in the descending colon, at the sigmoid flexure, the enlargement assumes very nearly the situation of an enlarged spleen, and is scarcely to be distinguished from it except by its peculiar feel, by its history, and by the result of cathartics; nor must one without the most persevering employment of purgatives and emetics, conclude that the intestines have been emptied.

The *kidney* sometimes enlarges towards the left hypochondrium, and presents a tumor very nearly in the situation of an enlarged spleen; but by tracing it back towards the loins, we shall find that its chief bulk is situated much farther back, and that it is much more fixed, so that if the patient is placed on his hands and knees it does not fall forward. By observing the rules (which I shall give you at my next lecture) for the diagnosis of ovarian tumors, you will easily distinguish them from enlarged spleen.

The Effect of Music on the Insane.—Dr. Boyd, in his nineteenth report on the Somerset Lunatic Asylum, determines affirmatively the vexed question of the propriety of amusements for the insane, and of the effect of music on the insane. He writes: "For a belief in the wonderfully soothing effects of music on the insane we have the authority of Holy Writ, in the case of King Saul; and the Greeks and Romans were equally aware with the Jews of its power. In modern times the effect which the 'Ranz de Vaches' produces on the Swiss, and the 'Reel of Tullochgorum' on the Highlanders, is well known. Music is said by Esquirol to act upon the physical system by producing gentle shocks upon the nerves, quickening the circulation. It acts upon the mind in fixing the attention by mild impressions, and in exciting the imagination by agreeable recollections. It is a valuable remedial agent, particularly in convalescence."—*British Medical Journal.*

Progress of Medical Science.

PREVENTION OF SICKNESS FROM CHLOROFORM. — A writer in the *British Medical Journal* believes that a few drops of chloroform in water, given as a drink to patients previous to their being anæsthetized, effectually counteracts the tendency to vomit, which is so annoying an accompaniment to most operations. The remedy has at least the claim of simplicity, and deserves to be tried.

NEW METHOD OF EXPELLING TÆNIA.—Dr. Lartet (*Gazette Médicale de Paris*) has tried with success the following method: He gives in one dose 20 grammes of ether, followed two hours afterwards by 30 grammes of castor oil. "The worm is discharged without causing pain, entire or almost so, and always with the cephalic end intact."

ALCOHOL UNNECESSARY IN the TREATMENT OF INEBRIATES —Dr. Day, Superintendent of the New York State Inebriate Asylum at Binghamton, says in a recent letter: "During the last ten years I have had under my care over two thousand five hundred cases of inebriety, in all its various forms and conditions. More than four hundred of these had delirium in its various stages. In the first years of my connection with the asylum for the treatment of their cases, I embraced the common error that liquor could not with safety be entirely withdrawn from the habitual drinker. After two or three years of observation, I found this was an error. * * * I found, on trial, that my patients did much better by withdrawing alcohol altogether, never allowing even alcoholic tinctures of any kind to be given. Since I have been connected with this institution (about five months) I do not think I have given one drop of alcohol in any shape to a patient. * * * A man may habitually drink his quart of liquor or more per day, as most habitual drinkers do. Confine such a man in some place and put him upon an allowance of one half his usual quantity, and he will suffer more than he will to cut him off entirely. I have tried this in a large number of cases, and have satisfied myself from actual observation."

SOLVENTS FOR CHOLESTERINE.—Dr. Buckler, of Baltimore, was consulted by a lady, who had always enjoyed good health up to the time of an attack of pain in the right hypochondrium, amounting at times to positive anguish. An examination revealed an irregular indurated tumor, felt through the walls of the abdomen, and directly over the inferior margin of the liver. The tumor was finally decided to be a distended gall-bladder filled with biliary calculi. A teaspoonful of chloroform was given by the stomach every hour while the pain lasted, and a teaspoonful after each meal for five days longer, when the tumor described entirely subsided, affording unmistakable evidence that the gall stones, none of which were found in the stools, had entirely dissolved by the use of the chloroform. An attack of the same nature as the former one coming on three months after, chloroform was again used, with the same result as before. It being desirable to administer some agent capable of controlling the cholesterine diathesis, succinic acid and peroxide of iron were prescribed as follows: ℞ Hydrated succinate of peroxide of iron, ʒ iss.; water, ʒ viss.; and of this a teaspoonful after each meal. The patient took of this six months with no recurrence of the attack, and has continued to enjoy excellent health. Three other cases treated with chloroform were promptly relieved.—*Am. Journal of Med. Science.*

ON THE INTERNAL USE OF CHLORINE WATER IN SCARLATINA ANGINOSA.—By C. C. Lee, M.D., of Philadelphia. —During an epidemic of scarlatina in Blockly Hospital, Philadelphia, the ordinary treatment seeming incapable of arresting the anginose symptoms, although the epidemic was not characterized by a specially malignant type, and the mortality in the first stage was rapidly increasing, attention was called to the efficiency of chlorine water in this condition. Eight severe cases—of twenty-three then on hand—were placed upon this treatment exclusively, as far as medication was concerned, milk punch, beef tea, etc., being continued as usual. The result of this change after the first twenty-four hours was most gratifying, for a marked improvement was perceptible in all the cases, without exception. The amelioration was first observed in the throat, where the sloughing tendency was rapidly arrested, and in the diminished inclination to coma, while the febrile symptoms and the eruption ran their course. All the eight recovered. Of the fifteen treated in the usual way, four died during the acute stage, and in two dropsical symptoms intervened during a protracted convalescence, to which they ultimately succumbed, leaving nine recoveries. In a subsequent epidemic, of twenty-one cases, twelve were selected at random, and treated with chlorine water, while the remainder were treated in the ordinary way. Of the former, two, whose symptoms were typhoid and malignant, died on the third day, without an effort at reaction, while the remaining ten made an excellent recovery. Of the latter, two died on the fourth and fifth day, with typhoid symptoms; one on the tenth day; two of kidney affection; and the remainder recovered rapidly. As is seen, the ratio of recoveries was almost two to one in favor of the chlorine treatment, and the cases were selected without reference to the severity of the symptoms: indeed, the only two cases of malignant scarlet fever that occurred, were included in this class; but the chlorine was quite powerless in arresting their progress. The chlorine water was used in several other cases, and the result was as gratifying as in the previous ones related. —*N. Y. Med. Journal.*

TAPEWORM TREATED WITH PUMPKIN SEEDS.—Dr. S. A. Williams relates the following history: A boy, six years old, had been troubled for about a year with tapeworm, segments of which had been frequently seen in his fæces. He had been treated with pink root, calomel, etc., but to no purpose. He was directed to take fifteen drops of turpentine, in the form of an emulsion, three times daily, for a week, and afterwards that two ounces of the kernels of pumpkin seeds be thoroughly ground up with sugar to a fine pulp, and sufficient mint water added to make an emulsion of twelve fluid ounces. This was taken in the morning, between six and seven, in divided doses, upon an empty stomach. At nine A.M. two tablespoonfuls of castor oil were given, and at eleven A.M. the usurper rapidly beat a retreat before the advancing foe, and twenty-one feet, *head and shoulders*, were carefully bottled up; since which time the boy has rapidly gained in health and spirits.—*Chicago Med. Examiner.*

BURNS.—The profession is indebted to Dr. Gross for the introduction of white lead and linseed oil in the treatment of burns. It is one of the very best applications that can be used; effectually excluding the air, and being always grateful to the patient. In all cases, no matter whether merely the skin or the deeper structures are involved, white lead rubbed up with linseed oil to the consistence of paste or paint, and placed on with a brush, will be found productive of great relief. There does not appear to be any risk from the

constitutional influence of the lead, though it has been suggested, to counteract any tendency of this kind, that the patient should occasionally take a little sulphate of magnesia.—*Dr. Agnew, in the Medical and Surgical Reporter.*

Sea-Sickness.—Dr. E. Andrews, in a letter to the *Chicago Med. Examiner*, states that persons subject to sea-sickness often take a voyage with entire comfort after taking the following prescription: Ten grains of blue mass the night before embarking; follow it the next morning with a brisk cathartic of Seidlitz powder. A voyage at sea is almost always constipating in its effects, and a repetition of the medicine once or twice on the passage may be necessary.

A New Anæsthetic.—Dr. S. P. Yandell, Jr., alludes to a new anæsthetic, the properties of which have been lately investigated by Dr. Smith, of London. He has administered *tetrachloride of carbon* with happy results in a variety of cases. It is inhaled, at intervals, to the extent of a drachm, and though the effect is transient, he has seen relief follow its use in headache, dysmenorrhœa, chronic metritis, and hay fever. He has also used it in labor, and found it a safe and valuable means of mitigating the pains, without apparently hindering the natural efforts. In some cases of labor, it induces a quiet sleep, and removes for a time the efforts of exhaustion of the nervous system. In many respects, Dr. Smith deems it preferable to chloroform—quite as safe, pleasanter to inhale, and producing the effect desired in smaller quantities.—*Atlanta Med. and Surg. Journal.*

Removal of Stone from Female Bladder by Dilatation—Dr. W. B. McGavran was consulted by a patient, who for two years previously had suffered from stone in the bladder. An operation being determined upon, the patient was put under the influence of chloroform, a sponge tent removed from the urethra introduced about an hour previously, and the little finger passed into the bladder to be reassured as to its size. The index finger was then substituted for the little finger, and by steady and continued pressure the urethra was dilated sufficiently to introduce a pair of forceps and seize the stones. After three trials, with the index finger in the vagina behind the stone, it was removed. There was but little laceration of the parts, and the patient recovered perfectly. The stone measured one and a quarter inches in length by seven-eighths of an inch in diameter, and weighed one hundred and fifty-six grains.—*Western Journal of Medicine.*

Several Recoveries from Tetanus have been recently put on record. Tobacco-juice applied to the wound (one case); Fleming's tinct. aconiti (two cases, a mare and a boy); acid. hydrocy. dil. (one case, a horse); and the extract of calabar bean (two cases); were the agents employed.—*Edinburgh Med. Journal, The Veterinarian, Braithwaite*, vol. liv.

The Relative Advantages of Lithotomy by the Median and the Lateral Methods.—Dr. Thomas Markoe has a very interesting article in the *New York Medical Journal* for April, 1867, on Median Lithotomy, with a report of twenty-three successful cases.

He believes that the advantages which the operation presents are—1st. The incision being in the median line of the body, does not encounter any large vessels, and must therefore be less liable to hæmorrhage than the lateral or bilateral operation. 2d. The incision being in the median line, and not reaching as far back as the veru montanum, cannot injure the seminal ducts, and therefore produce emasculation. 3d. With the finger in the rectum, the course of the knife can be most precisely appreciated, and ordinary caution only is necessary to avoid wounding the gut in the first plunge of the knife. 4th. There is no danger that the incision may fail to reach the bladder. 5th. The deep perineal fascia not being invaded by the knife, deep infiltration of urine cannot occur. 6th. The prostate, not having been divided, retains its sphincter power, and the urine does not flow from the bladder except at the will of the patient.

Mr. Holmes Coote (*Lancet*, Feb. 2), who advocates the lateral method, holds that, in the unfortunate cases, the causes of death depend but little on the casualties attending the operation. They proceed from the all-pervading influence of morbid changes in important parts, such as the kidney, and upon the organism generally. The median operation has been tried at St. Bartholomew's in various ways, but none had appeared to him to possess any claim to superiority over the lateral operation. The operation of lithotrity is best suited for calculi of medium size, occurring in persons otherwise healthy, in middle or advanced life.

Mr. W. F. Teevan (*Brit. and Foreign Med. Chir. Review*, Jan. 1867), arrives at the following conclusions: 1. When lateral lithotomy is performed, the stone ought always to be cut out, and not torn out. 2. That the median operation is not justifiable for the extraction of calculi which are upwards of half an inch in diameter; for if such sized stones be removed by that process, obliteration of the orifices of the ejaculatory ducts and permanent impotence will result.

Poisoning by a Bee-sting.—Dr. William O'Doniel, of Marion, Georgia, was called at 10 A.M. to see a gentleman of feeble constitution, who, about half an hour previously, had been stung by a bee on the right ear. The sting was immediately removed, after which the patient was troubled with nausea and occasional emesis, which continued to grow worse. After careful examination, found patient irrational, heart's action much enfeebled, breathing exceedingly difficult and stertorous, profuse flow of saliva, face considerably swollen, body partially covered with dark spots, extremities cold. Ordered sinapisms to extremities, morphia one-quarter gr, brandy and water *pro re nata*. In an hour the patient could speak rationally, and complained of a most excruciating pain in the epigastric region, chilly sensation, burning in fauces, and incessant nausea. By 4 P.M. patient was up, but much exhausted, and recovered completely.—*Atlanta Med. & Surg. Jour.*

Poisoning by Acetic Acid.—A case of this rare accident recently occurred to a man forty years of age, who according to accounts, took, while intoxicated, two or three ounces at a single draught for suicidal purposes. The patient was shortly afterwards admitted to Guy's Hospital.

The following is an abstract of the lengthy case: Within the first hour the symptoms were slight collapse and laryngeal obstruction, which was so severe as to lead to cessation of respiration, but was at once relieved by tracheotomy. The lips and tongue were not at all charred or inflamed. Some six hours subsequently reaction was complete; there was inability to swallow, with great thirst. On the following day the patient could swallow liquids, but had pain at the fauces, and considerable salivation. On the third day the tracheotomy tube was taken out, without any subsequent impediment to respiration. No symptoms of gastric, pulmonary, or cardiac disturbance arose. Indeed, divesting the case of the laryngeal complication (which, perhaps, would not have arisen had the man been sober when swallowing the acid), we find the symptoms were

simply slight collapse, an inability to swallow during one day, and thirst and salivation; but it must be borne in mind that the result was in all likelihood modified by the early and copious administration of magnesia suspended in water.—*Lancet.*

Inoculations of Melanotic Matter.—M. Goujon has lately succeeded in producing melanotic deposits in rabbits by inoculating the matter taken from a tumor of that nature removed from the axilla of a patient. If subsequent experiments confirm the results obtained by M. Goujon, a reconsideration of our views as to malignant growths will become necessary.

A New Styptic.—An exchange says that the perchloride of iron combined with collodion is a good hæmostatic for wounds, the bite of leeches, etc. To prepare it, one part of crystallized perchloride of iron is mixed with six parts of collodion. The perchloride of iron should be added gradually and carefully, to prevent the evolution of excessive heat, which injures the collodion. The composition, when well made, is of a yellowish red color, perfectly limpid, and produces on the skin a yellow pellicle which retains great elasticity.

Fermented Mare's Milk in the Treatment of Phthisis.—At a late sitting of the French Academy of Medicine, Dr. Stahlberg, physician to the factories of Sorga in the Oural, read a paper on the efficacy of *koomiss*, or fermented mare's milk, in the treatment of pulmonary diseases. Its good effects can only be explained by its producing a diminution in the secretion of the mucous membranes or a better nourishment.

Chloroform in Obstetrics.—Sir J. Y. Simpson gave as his opinion, at a meeting of the Obstetrical Section of the British Medical Association, that chloroform never caused convulsions, puerperal mania, hæmorrhage, or delay of labor. "He gave it as soon as weariness from pain occurred, during a pain, and always with the patient in a recumbent position."

The Cause of Osteomalacia.—M. Drivon, after several analyses, has concluded that in osteomalacia the presence of lactic acid and the lactates in the bones, by acting as solvents of the phosphates and carbonates, is the cause of the softening.

Ingrowing Toe-Nail.—Dr. Bailey (*Leavenworth Medical Journal*) having observed that the pressure of the second toe against, and rather beneath, the great toe, is the source of the whole trouble, has devised a bandage for the relief of the difficulty. He takes "a piece of strong muslin, about one inch wide and just long enough to make two loops (by sewing), one large enough to slip over the great toe, and the other to slip over the third toe and bring them close together, letting the second toe rest over or above the bandage." In this way he gets the pressure required to crowd the soft parts away from the nail, and at the same time removes the pressure which caused the disease. This bandage may be easily worn, even when the boots or shoes are ordinarily tight.

Foreign Body in the Urethra.—Dr. Charles Washburne, House-Surgeon N. Y. Hospital (*Medical Gazette*), recently extracted, in the case of a patient with a stricture just under the pubic arch, about one and a half inches of a No. 6 elastic bougie, which was broken off beyond the stricture, after having been introduced with difficulty by another physician. Dr. W. resorted to the following ingenious device: "The patient was etherized, and a strong needle passed through the walls of the urethra from below and behind the stricture into the fragment of the bougie, which was moved along the urethra, and after a little difficulty through the stricture, to a point where it could be reached by a polypus forceps introduced through the meatus." No bad symptoms followed, and after the patient's discharge from hospital, dilatation was resumed.

Wounds produced by the Chassepot Projectile.—Dr. Sarazin, of Strasburg, has made some experiments on a corpse at close quarters, with the following results: 1st. The diameter of the orifice made by the bullet entering the body, is not sensibly larger than that of the projectile. 2d. The diameter of the orifice by which the bullet leaves the body, is from seven to thirteen times larger than that of the projectile. 3d. The arteries and veins are cut transversely, retracted and gaping; the muscles torn and reduced to a pulp. 4th. The bones are smashed in a manner out of all proportion with the dimensions of the projectile. To sum up, the wounding effects present a remarkable intensity, and it is well to note that the balls, after passing through the body, pierced two one-inch planks and buried themselves deeply in the wall behind.

Ascites dependent on Hepatic Lesion; Operation of Paracentesis twice performed; followed by Peritonitis;—Cure.—Dr. de Faria, Professor of Clinical Medicine, reports the following case:

José, African, bachelor, twenty years of age, free, a stone-cutter by trade, and an inhabitant of the parish of San Pedro Velho, on the 11th of March of the current year, entered the Infirmary of San Francis during my term of service. On examining the patient I remarked a general condition denoting a progressing cachexia; on exploring the belly an enormous swelling was discovered, on percussing which I determined great peritoneal involvement and complication. I likewise detected in the right hypochondriac region a firm hard body sufficiently well pronounced, where, though with great difficulty, I determined by palpation the liver much augmented in volume, and extending far above the borders of the false ribs. Respiration was not sufficiently accelerated in the vertices of the lungs, and was quite indistinct at the bases, where marked signs of vesicular congestion were apparent. The heart showed nothing abnormal in its action, save an unwonted celerity in its rhythm, and an unusual soft sighing near its base, dependent no doubt on an alteration in the blood. The inferior extremities were œdematous; the pulse was weak and frequent. I instituted at once drastic purgatives and decided diuretics; and directed a dietetic regimen, graduated to suit his failing digestive powers—such as chicken, bread, and a small quantity of wine for dinner. The enormous enlargement increased so rapidly as to become minute by minute a horrible inconvenience to the poor man, impeding ordinary repose, and absolutely forbidding sleep; and his countenance portrayed so much suffering and anguish that I determined to perform the operation of paracentesis. For the reasons given above, I performed the operation as soon as the day following his entrance into the hospital. A very large quantity of a peculiar serum was evacuated. Afterwards I continued, during my month of service, my therapeutical remedies without stint; yet notwithstanding all I could do, the liquid reproduced so rapidly that on the 19th day of my month, a new puncture was necessitated; and on the 20th day unequivocal signs of acute peritonitis appeared. I forthwith commenced to combat this with calomel in small doses, and opium, with mercurial frictions, etc. The inflammation subsided after a few days, and from that date I began to administer the perchloride of iron, in conjunction with a mild diuretic and sudorific, composed of cream of tartar, nitre, and the alcoholic extract of aconite. From that date until the day

of his departure, well and sound, I continued this treatment; having, however, to these therapeutical means added a generous reparative diet.—*Gazeta Medica da Bahia, 10th June*, 1867.

Epilepsy conjoined with Congenital Phymosis.—Congenital phymosis has been observed in eleven of twenty-five consecutive male cases of epilepsy admitted at the infirmary. That such a frequent complication should hitherto have remained unnoticed can only be explained by the circumstance that epileptic patients seldom come under the eye of the surgeon, and that physicians usually neglect to examine the sexual organs. The effects of congenital phymosis on the system are usually disregarded, although there can be little doubt that this malformation has a considerable pathological importance. There is always an accumulation of serum between the prepuce and the glans in such cases, and herpes and balanitis may be the consequence. This irritation often leads to great sexual excitement about the period of puberty, and to masturbation, with all its consequent evil effects; frequent emissions of semen at night may also be traced to the same cause. A variety of cerebral symptoms may then be induced, such as pain in the head, giddiness, noises in the ears, eructations, sickness, etc., which, where they depend only on this condition, may be entirely removed by circumcision. Whether actual epileptic fits are ever the result of phymosis, seems doubtful; yet the propriety of operation in cases of that kind cannot be questioned, as all sources of inflammation should, on principle, be removed in convulsive disorders. Several of these cases which were admitted at the Infirmary, have been operated on by Mr. Solly and Mr. Spencer Wells. In no instance, however, have the fits ceased immediately, consequent upon the operation, so that a relation as between cause and effect could not have existed between phymosis and epilepsy. Yet, Dr. Althaus said, it generally seemed as if the convulsive disorder, after circumcision in such cases, yielded more readily to the remedy employed than it did before.—*London Lancet.*

Hermetic Seal.—A mixture of gelatine and glycerine is liquid while hot, but on cooling it becomes solid, retaining considerable elasticity and toughness. The neck of a bottle dipped into this melted compound is covered with an air-tight cap, which can be made as thick as desired by repeating the operation.

Preserving Sulphuretted Hydrogen in Solution.—At the last meeting of the Pharmaceutical Society of Paris, M. Lepage brought forward a process which he has adopted for preserving solutions of sulphuretted hydrogen. Instead of using water alone, he saturates a mixture of equal parts of pure glycerine and water with sulphuretted hydrogen gas, and uses it in the ordinary way. None of the reactions are in the least interfered with, while the solution possesses almost perfect stability. The dilute glycerine dissolves less gas than distilled water will; representing the solubility in water by 100, that in glycerine will be 60.—*Chemical News.*

Artificial Milk.—Liebig recommends the following "Alimentary Preparation for replacing Human Milk for Children:" A mixture is made of 15 grammes of wheaten flour, 15 grammes of ground malt, 6 grammes of bicarbonate of potash, 30 grammes of water, and 150 grammes of milk are then added. The whole is then heated, and then stirred continually until the mixture begins to thicken. It is then taken off the fire, and stirred all the while. After five minutes it is boiled, and then strained through a fine sieve. The ground malt necessary for the preparation is easily furnished from barley malt, obtained at any brewery. It can be ground in a common coffee grinder, and then passed through a sieve. If this preparation is well made, it is as sweet as the natural milk; it is fluid enough, and keeps for twenty-four hours. In Germany the use of this food is very extensive, and its nutritive qualities are found to be excellent. It has a slight taste of flour or malt, to which children get accustomed—in fact they soon prefer it to other food.—*Chemical News.*

Glycerine in the Arts.—A German chemist, named Pusher, of Nuremberg, reported to the Trades Union of that place that he had met with great success in using glycerine together with glue. While generally, after the drying of glue, the thing to which it is applied is liable to break, tear, or spring off, if a quantity of glycerine equal to a quarter of the quantity of glue be mixed with it, that defect will entirely disappear. Pusher also makes use of this glue as lining for leather, for making globe frames, and for smoothing parchment and chalk paper. He also uses it for polishing, mixing wax with the glycerine, and using it as an underground for laying on aniline red color. The red was found to excel all others in which glycerine was not used. The glycerine has also some properties in common with India-rubber, for it will blot out pencil marks from paper, so as to leave no mark whatever. A paste made of starch, glycerine, and gypsum, will maintain its plasticity and adhesiveness longer than any other known cement, and does therefore recommend itself for cementing chemical instruments and apparatus used by pharmacists.—*Journal of Applied Chemistry.*

Chemical Calculus.—Sir Benj. C. Brodie, Professor of Chemistry in the University of Oxford, in a lecture "On the mode of representation afforded by chemical calculus as contrasted with the Atomic Theory," assumes as his unit that portion of ponderable matter which at the melting point of ice and at a pressure of 760 millimetres of mercury, occupies a space of 1,000 cubic centimetres. To denote units of chemical substances, he uses Greek letters as symbo's, and in such a manner as to indicate that nitrogen, phosphorus, chlorine, bromine, iodine, and several other so-called elementary substances, are compounds containing hydrogen, in combination with unknown elements. It is claimed that this system shows there are three, and perhaps four, fundamentally distinct classes of elemental bodies; the first may be represented by hydrogen and mercury; the second by oxygen and sulphur; the third by nitrogen and chlorine. The only novelty in this classification is the grouping together of elements of widely differing "atomicity." What advantages may be gained by assuming that substances not yet decomposed are compounds, and using symbols of volumetric units as a more mathematical form of expression, the author has not yet satisfactorily shown.

Effects of Alcohol on the System.—Dr. N. S. Davis (*Chicago Medical Examiner*), in a series of sphygmographic observations in regard to the above, has concluded, in the first place, that the presence of alcohol in the blood diminishes the rapidity of nutrition and disintegration, upon which depend the functions of elimination, calorification, and innervation. In other words, alcohol is a positive organic sedative instead of a diffusive stimulant. In the second place, the alcohol itself acts in the system exclusively as a foreign substance, and as such is ultimately excreted or eliminated without chemical change.

A Double Femoral Artery complicated an operation for ligation—the second case on record—at the Richmond Hospital, London.

MEDICAL AUTHORSHIP.

"A GOOD book," says Milton, in his beautiful essay on the Liberty of Unlicensed Printing, "is the life-blood of a master-spirit, embalmed and treasured up on purpose to a life beyond life."

It is unfortunate for the cause of science that more of the pure and noble ambition that inspired the great poet to labor over a decade of years on the epic that has immortalized his name, is not felt by the skilful and laborious medical profession of America. It is unfortunate that, amid the rush and din of a growing republic, even our men of science have been forced to labor so much for the meat that perisheth, and have sought so little the bright, though distant, rewards of fame.

It is unfortunate for the progress of the American profession itself, that, amid the first material development of the nation, they have thus been compelled to minister so exclusively to the needs of the living, that little time or strength has been left to appeal to, or to seek for glory from generations yet unborn.

But this national exigency, at least in the Eastern part of the country, has in a measure passed away, and the forty thousand physicians of America are no longer without excuse, if either a love of duty or a love of fame does not inspire them to erect a higher and severer standard of medical literature.

We have passed through a stage of our material growth; we have levelled the forests, built our houses, and opened our highways; we are sure of bread for ourselves, we are sure of it for our children; and, if we can turn awhile from the race for wealth, we may bequeathe to the hereafter something purer, richer, and more enduring than mere physical comforts.

To speak plainly, the day has come when the profession should labor less for money and more for science. We should cease to be mere mechanics, working only for hire, and should rise to the level of scientific thought, philosophy, and authorship. We cannot do this without sacrificing a few pieces of silver. But is a man worthy of the profession who will not risk this much? "Science is a harsh mistress," said Sir Humphry Davy, when the youthful Faraday asked to be his assistant. "She gives but small pecuniary rewards. Consider well before you leave your prospect of wealth as a merchant for the poverty that awaits the servants of science."

Faraday left his store, however, and entered the laboratory, and created an era in the history of civilization. This is the spirit, this the enthusiasm that inspires us in this land far too little.

To raise the standard of medical authorship is a duty every right-minded physician owes to himself.

A distinguished medical professor, whose works have long been standard on both sides of the Atlantic, once said to us that he never felt that he "really knew any subject until he had written upon it." The oft-cited words of Bacon, "Writing makes an exact man," are preëminently true of all scientific attainments. We can never thoroughly know any subject until we have first thoroughly learned our ignorance of it; and one of the very best ways to gain a measure of our own ignorance is to attempt to teach others.

We speak advisedly when we say that any young man who carefully and studiously writes or lectures on any department of science, will make greater progress in five years than another man of equal ability can do in twenty-five years without the use of his voice or pen.

Our ideal of medical rhetoric is most criminally low. It seems to be a common impression, even among those whose education should have taught them better, that the detailing and representation of cases, and all scientific writing generally, is wholly a mechanical performance, and requires no special rhetorical training or study. The error is a most serious one, and makes itself felt in the hideous compositions that load the tables of every editor of a medical journal.

We have a right to speak plainly here. There is not a medical college that does not have one or more professors who ignorantly teach erroneous styles of grammar and rhetoric; there is not a class that graduates from any of these institutions one quarter of whose members can prepare a paper on any subject that shall be, both in thought and style, a credit to themselves and to the cause of science; there is not a medical journal that is not forced to publish articles that must be revised, sentence by sentence, before they appear in print; there is not a medical society whose members are not more or less oppressed by diffuse and shambling addresses.

The effect of the almost universal prevalence of a low standard of our medical writing and speaking has recoiled banefully on the estimation in which the profession are held by the community. The impression prevails, even among the educated classes, that medicine is an art and not a science, and that its disciples are mechanics, and cannot be scholars. The ranks of the profession are swelled by a great army of Ishmaelites, who, wandering over the earth, by some luck or chance happen to stumble into "doctoring," and who feel

about as much scientific enthusiasm as do the Patricks who lay the pavement, or the "bulls and bears" in Wall street.

Our literary institutions send to our medical schools, with a few slight exceptions, those whom they endured or hated, rather than those whom they loved and honored; the fools and the drones, rather than the gentlemen and the scholars; the leaves that have been shaken off before the maturity of graduating was reached, rather than the fairest and best of their perfectly riper fruit.

There are, indeed, already in the profession—and we are glad to see that each year is adding to their number—a few of as true, as pure, as noble and aspiring souls as ever connected themselves with any cause, but as yet they are hardly enough to leaven the great mass of ignorance and mediocrity.

We received the other day from a very faithful, earnest gentleman in the profession, an article on a subject of great interest, which included some exceedingly interesting observations, but which contained so much that was irrelevant, and was prepared throughout in such utter defiance of the laws of grammar and rhetoric, that we were compelled to return it to its author, with the request that it should be entirely remodelled.

Whoever says that scientific writing is a very easy or indifferent matter, is either a genius or a fool. In the accurate observation of causes, symptoms, and results of disease, in making the philosophical deductions from established facts, by rejecting the irrelevant and considering what are essential; and in presenting these facts and conclusions in a style at once simple, clear, and interesting, there is room for the display of the best faculties of observation and judgment, and as wide a range for the exercise of rhetorical genius and ability as in any other form of literary composition.

"Genius," says Ruskin, "seizes right hold of the heart of a subject." The same is true of all with cultivated talent. Ability in composition does not come by accident. It does not come by genius unless it be accompanied with patient industry. It does not come by academical or collegiate education. It comes by the patient study of the best models, by faithful and repeated practice. Indeed, success in this, as in other fields of effort, comes through repeated failures.

Furthermore—authorship is a duty that physicians owe to their profession. The obligations that all practitioners owe to science are greater than they can ever repay, however sincere may be their gratitude. It is through a long line of authors that we have inherited all that we know in the various departments of medicine and surgery. It is to medical authors that we are indebted for the garnering up and treasuring of the accumulated experience of more than twenty centuries. It is by the teachings of medical authors that many of the best discoveries and improvements of science have been suggested and inspired. It is, in a word, by authorship, more than by anything else, that the practice of our day is more rational, more discriminating, and more successful than that of Hippocrates and Galen.

While it is true that very much is published in our journals that ought never to see the light, it is still more true that much valuable experience is lost to the world, perhaps for ever, for want of a trifling amount of literary ability and enthusiasm on the part of the observer. A great deal that is rich and suggestive in medical practice dies in the various circuits of our country practitioners, and is buried with them in the same grave.

To record this experience, and to transmit it to the future, is not a matter of choice. It becomes a solemn and imperative duty. The hour a graduate receives his diploma and enters the ranks of the profession, that hour he consecrates himself to science; and so long as he continues in her service he is bound at least to obey her one great command: "Go and teach what you learn to every member of your own profession." The sweetest, purest, noblest things in the profession of modern times, and that which redeems its many bickerings and envyings, its occasional bigotry and narrowness, is the universal *esprit de corps* that makes the discoveries and experience of the individual the common property of all. The feeling with every pioneer is, "This is not *my* invention, these are not *my* experiments; they are the property of Science, and I am to bring them as grateful offerings into her temple."

But there are those who may not be influenced by appeals to love of duty. For these we must descend to a lower level, and, with the old Romans, plead with them to do right, for the love of glory. Amid the harassments and drudgery of daily practice can there be anything more sustaining than the reflection that we are toiling not alone for this little circle of patients about us, but for the misery and distress everywhere; not for the brief day of our personal activity, but perhaps for all coming time.

This may be a lofty ideal, and few there are who shall attain unto it. But there is a world of wisdom in the advice that Dr. Dwight loved to give, "*Aim high*, for you will be sure to come short of your aim."

But we descend to a still lower level, and appeal to necessity. It is only by writing that young men of our time can hope to rise to high position. It is fast becoming true of America, as it has long been true of Continental Europe, that only authors can become authorities. "What has he written?" is the question first asked of a candidate for a professorship in Berlin, Paris, or Vienna. With us it has been the custom to inquire, "What influence can he bring? who are his bankers? what is his income-tax?"

But we are happy to say that a new era is commencing to dawn on the science of America. The time will soon be past when any man can be bolstered up into scientific greatness, and held there by friendly props and stays. The time will soon be past when

the professional standing of any man will be solely or chiefly estimated by the carriages he drives, the dress of the patients that crowd his waiting-rooms, or even by his mere mechanical skill.

The time is already past when any man can hope to rise to be authority in any department of medical science through any royal road of social influence, political manipulations, or even of personal charms. Those who are to be the leaders and guides of medical science for the coming generation must earn their position by persistent, original investigation, and by faithfully recording their experience in the permanent literature of the day.

It is the pen and not the lancet, the scholar and not the mechanic, that is to guide and shape the scientific future of America.

THE attendance of students at our colleges is not, on the whole, so large as was at first anticipated, and thus far there is no increase over last year. What we lack, however, in quantity, is amply compensated for in quality, and the various institutions have reason to congratulate themselves upon the fact that so large a number of well-informed and properly-prepared students have enrolled themselves as matriculants. We have reason to hope that eventually the medical student of old will be effectually and permanently replaced by his more accomplished and perhaps more civilized brother. The time is even now at hand when it is next to impossible to distinguish any student of medicine from an accomplished and well-bred gentleman; the proverbial cane is going out of fashion, the straggling locks have been shorn, and all the other eccentricities of the bygone "Sawbones" have ceased to be. We have reason to believe, in spite of this change, that our students will work as hard and progress as rapidly as they did formerly.

A PLAN for instruction in special departments of medicine is about being inaugurated in Boston, which, if fully carried out, will doubtless be productive of much good in extending the limits of medical education. The idea is to furnish young graduates and practitioners opportunities for perfecting that knowledge of the healing art which the rapid advancements in science have placed beyond the ordinary college curriculum. On general principles, there is every reason why the project should meet with success, and we should like to see similar institutions in all our large cities.

The profession in this country should commence to develop its resources more than it has heretofore done, and endeavor to prove in a practical manner that it is not always necessary to go abroad in order to familiarize ourselves with the higher walks of the healing art. But aside from the gratification of a natural and commendable pride in this matter, the teachers have another responsibility to discharge, that of ministering to the wants and requirements of those who are unable to spend any time abroad, and who, if they were, are too imperfectly acquainted with the French and German to render such a sojourn profitable or edifying.

The school in question has a good faculty, the majority of its members being men of distinction in the different departments which they are to teach.

Reviews and Notices of Books.

THE PHYSIOLOGY OF MAN: DESIGNED TO REPRESENT THE EXISTING STATE OF PHYSIOLOGICAL SCIENCE AS APPLIED TO THE FUNCTIONS OF THE HUMAN BODY. By AUSTIN FLINT, JR., M.D., Prof. of Physiology and Microscopy in the Bellevue Hospital Medical College, N. Y.; and in the Long Island College Hospital, etc., etc. Alimentation, Digestion, Absorption, Lymph, and Chyle. New York: D. Appleton & Co. 1867. 8vo., pp. 546.

A LITTLE over a year ago we took occasion to notice somewhat in detail the contents of the first volume of a series upon the Physiology of Man, by Prof. Flint, Jr. We are now called upon to bring before our readers a cursory review of the contents of a second volume, and reiterate our satisfaction at the manner in which the task which he has taken upon himself has been performed. The intention of the author is to furnish at such intervals as are consistent with careful study and investigation, four volumes upon the different departments in physiology, and, if possible, to make each part complete in itself. The first volume treated of the blood, circulation, and respiration, and was well calculated, by the manner in which the subject was dealt with, to prepare the profession for a just appreciation of the second of the series now before us.

The subjects of alimentation, digestion, and absorption, have necessarily an interest attached to them commensurate with the importance of their functions in the preservation of animal life; but, strange to say, works on physiology generally, have not been accustomed to give them that prominence and detail of treatment which all practising physicians acknowledge they deserve. For the present efforts of our author in supplying this deficiency, his professional brethren must necessarily be under obligations. The different subjects are handled with care, discretion, and ability; while the amount of study which has been required to personally acquaint himself, as he claims to have done, with all the numerous authorities mentioned throughout the work is difficult to estimate. Such a course for a practical teacher and author cannot be too highly commended, and must of necessity add that weight to his statements, and give that force to his conclusions, which nothing short of a rightful determination to do his duty could. But not only have the older authorities been carefully perused, but recent writers have been studied, and all the late and most important discoveries are brought up to date.

The first section of the work, treating of alimentation, is very complete and systematic. The remarks upon hunger and thirst are full of suggestive and practical facts, and cannot fail to interest the reader. The description of the proximate principles, of course inevitable, will perhaps be read more than chapters on those subjects ordinarily are, on account of the many well digested ideas concerning their physiological actions which are plentifully sprinkled throughout the text. The relations of the different alimentary substances to each other, their proper mode of preparation, and their relative value, are fully presented. The account of the cereal grains in Chapter III. is elaborately given, while

the remarks upon the different beverages in Chapter IV. give evidence of much careful analysis and studious elaboration. His views upon the different stimulants are eminently sound, and in keeping with those advanced by most of the leading authorities. Alcohol, then, is not considered as an aliment in a physiological sense, its principal effect upon the economy being the production of a certain amount of nervous exaltation, which passes off as the article is eliminated, together with the diminution of exhaled carbonic acid gas, and the discharge of other excrementitious materials, the principal among which is urea. The argument to prove that alcohol does not increase the capacity to endure severe and protracted bodily exertion, is not as specious as it might be made by a less absolute reliance upon the testimony of Dr. Hayes, of the Arctic exploring expedition. But while one may find fault with the line of argument, the conclusions of the author will be accepted on grounds already well established.

The physiology of digestion is considered under the appropriate headings of salivary, gastric, pancreatic, biliary, and intestinal. While each subject is treated almost exhaustively, and all the important experiments recited and commented upon, no new conclusions as to the functions of either of the foregoing secretions have been arrived at; the saliva converts starch into sugar; the gastric juice (together with its accompanying acidity, due, as the author thinks, to free lactic acid) digests the albuminoid substances; the pancreas takes care of the fats; the intestinal juices help along the saliva in the conversion of the starch; the bile, though acknowledged to be a secretion of vital importance, is still, as regards its function, wrapped in tantalizing mystery.

The consideration of digestion from a mechanical point of view is very complete and satisfactory, and especially is this the case with the remarks upon deglutition and the movements of the stomach. In the latter connection we cannot forbear our hearty commendation of the manner in which the function of vomiting is handled. The interesting and valuable experiments which are detailed, are conclusive. In them we learn that the diaphragm is the principal agent in vomiting, and that this muscle is aided by the abdominal muscles, the muscular coats of the stomach being at the time relaxed. These facts have been long ago established to the satisfaction of physiologists, but we do not recollect to have seen them so succinctly and comprehensively put before.

Absorption is most elaborately discussed, and although many facts of value are given, they are hardly sufficient to divest the article of tediousness. But this is, after all, nothing more than the general reader expects from an enthusiastic physiologist.

The book as a whole is an admirable one, and is even a decided improvement upon the first. The interesting feature of the work is a recital of typical experiments, which are timely and judiciously introduced to impress the facts upon the mind of the reader. It is printed in elegant style, and may be considered a model in the typographical line.

Manual Compression in Aneurism.—Mr. Thomas Bryant, of London (*Lancet*), has succeeded in curing a large aneurism of the popliteal artery by manual pressure, in twenty-four hours.

The Society for the Prevention of Cruelty to Animals (London), has voted the sum of twenty-five pounds to the Richardson testimonial fund, in consideration of his discovery of the method of producing local anæsthesia.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Oct. 23, 1867.

Dr. H. B. Sands, President, in the Chair.

Dr. A. Clark presented a specimen of tumor of the brain for the sake of bringing out some points connected with diagnosis. The chief features of the case he then read as reported by Dr. C. Young, the House Physician of Bellevue Hospital.

SOME POINTS CONNECTED WITH THE DIAGNOSIS OF TUMOR OF THE BRAIN.

Elizabeth Lambert, æt. 33, a native of Wales, widowed, admitted July 25, 1867. When admitted, patient was in a very exhausted condition, and had to be carried to a ward. She stated that she had lived for some time in Charleston, and had been attacked at different times by the miasmatic fevers which prevail there. She gave a history of tubercular family taint. She had had several children, had never contracted chancre, and gave no history of secondary syphilis. She had recently been discharged from Charity Hospital, where she said she had been treated for phthisis. Patient said that she had been subject to violent headaches for the past fifteen years, but that her general health had been good till last Christmas, when she contracted a cold, and suffered from dyspnœa, palpitation of the heart, and spitting of blood. She had no cough. She had suffered from night-sweats, had lost flesh and strength.

At time of admission she complained of nothing but weakness. Face pale, pupils natural, pulse feeble and rapid. On percussion there was slight comparative dulness on right side. On auscultation nothing abnormal was discoverable beyond feeble respiratory murmur and prolonged expiration on both sides. No increase of vocal resonance. Heart sounds were healthy. No disease of liver or spleen could be diagnosticated, urine normal. Shortly after admission she began to complain of severe neuralgic pains in the head, more especially on the left side and at the back. This was treated with quinine in large doses, when she recovered sufficiently to be up and "go out on pass." Her improvement continued for about three weeks. About October 1st, she again began to suffer with the pain. There was ptosis of left eyelid, and there was a slight ecchymosis of the integument around it. The pupil was somewhat dilated and did not respond to light. There was some tenderness of the supra-orbital nerve. There was no facial paralysis, and the tongue was protruded in the median line. The right eye was natural. She complained of a terrible pain also at back of her head. For about ten days previous to death she had occasional vomiting. The bowels had to be moved by medicine. The pulse was slow, sixty-four, and regular. The pain did not yield as before to quinine, and she was at last put on large doses of iron, with iodide of potassium in large doses, on suspicion of there being a cerebral tumor. She died October 22.

Autopsy thirty hours after death.—Rigor mortis well marked. The calvarium was removed, and the dura mater found to be adherent on the left side, posteriorly. It was carefully removed, when there was found a large tumor adherent to dura mater, hard, and occupying a deep depression in the left hemisphere of brain. The brain-matter was so much softened that it could not be removed, and the exact relations were thus destroyed. The lungs were found to present the appearances of subpleural emphysema. Aorta was slightly atheromatous, as it is given off from heart. Heart healthy; liver, kidneys and spleen healthy.

The main point in the case being pain on the left side and at the back of the head, Dr. Clark had remarked to the House Physician, at the time his attention was first drawn to the patient, that the cause of the symptom was to be referred either to the existence of miasmatic neuralgia, or to a tumor of the brain probably syphilitic in character. He was then informed that the patient had previously been an inmate of Bellevue, and had been treated by quinine for neuralgia, and that she had shortly after gone out relieved; and she being re-admitted with the same pain on the 1st of October, the doctor was inclined to take the view that it was miasmatic, and he held to that opinion until his faith in it was shaken a few days before her death. The death was sudden, occurring on the 22d inst., and nobody knew the precise circumstances attending it.

On being informed of her death, the professor was much surprised, as he had seen her the day before with her intellect clear and motor power good, she having at that time no evidences of organic disease of the brain. When, however, he was told that shortly before her decease there was noticed a little ptosis of the left eye, with some ecchymosis, he was forced to change his view of the case, and pronounce the cause of death as tumor of the brain.

On making a post-mortem examination, a tumor was found growing out from the dura mater, and pressing into the substance of the brain at the posterior extremity of the posterior lobe of the cerebrum. The hole into which the tumor was imbedded was large enough to receive half a hen's egg. Although there was considerable softening in the neighboring brain substance, there was none at that precise point.

The pulse was slow during the latter part of her life; at sixty, and perhaps rarely above that. Her mode of death, however, was a point to which he wished to call the attention of the Society, in the hope of obtaining some explanation for the association of the symptoms referrible to the left eye, with the tumor on the brain. In a word, how could a tumor in this locality produce a contraction of the pupil, ptosis, and ecchymosis of the eye referred to? The other eye was reported sound.

As to the nature of the tumor, as no microscopical examination had as yet been made of it, nothing but conjecture could be offered. It might be of tuberculous or fibrous character.

Dr. Flint asked if the softening was in any proximity to the origin of the third pair of nerves.

Dr. Hamilton did not think it was necessary, in order to make out a distinct connection between cause and effect, to suppose that the origins of the nerves in question were involved, and referred to some observations recently made by Brown-Séquard, in which it was proved, that nerves more or less remote from the seat of brain-disease were affected, and this without any cause that could be explained on the score of nervous communication, save reflex action.

Dr. Jacobi thought that the sudden death might be explained on the supposition of the existence of centric apoplexy, as he noticed that the brain had not been cut into.

Dr. Clark remarked that it was designed not to examine the brain farther until it had been exhibited to the Society.

Dr. Jacobi also suggested that some explanation of the direct cause of death might be found in the upper part of the spinal cord.

Dr. Clark stated that the case, to his mind, was one which, so far as it was investigated, could give no clue for the formation of a correct diagnosis before death.

Dr. Jacobi thought that this difficulty was increased by a knowledge of the fact that the paralysis of the levator oculi, and of the radiating fibres of the iris, were respectively due to different causes.

In answer to a question from Dr. Flint, Dr. Clark stated that the heart was not fatty.

Dr. Hamilton, in reference to the question of sudden death, reminded the Society of some observations made by Dr. Flint some years ago, bearing upon effusion into the arachnoid of the fourth ventricle as the cause.

Dr. Flint remarked, that since the time those observations were published, he had reason to reject them as without value, more especially as subsequently the subject of uræmia had been studied.

BIRTH OF CHILD A YEAR AFTER OVARIOTOMY.

Dr. Cutter, in rising to exhibit some serum removed from an ovarian cyst, took occasion to refer to a case of a lady twenty-four years of age, from whom he had removed a year before a multilocular tumor of the left ovary. She made a very rapid recovery, and on the 8th of October was delivered of a healthy female child without difficulty. He knew of but few cases where pregnancy followed after such an operation, and none in which it had occurred so soon after. Mr. Spencer Wells, out of 228 cases, had met with only eight or ten pregnancies.

The serum presented was removed from the left ovary of a lady thirty-four years of age. The tumor had been growing for ten years, during which time she had two children, and was now pregnant with the third; at the time of the tapping she was quite large, and the amount of fluid withdrawn was seventy pounds. She suffered no inconvenience from the tapping, although she had commenced to refill rapidly. As she was advanced seven months, the question arose as to whether it was best to induce miscarriage or allow the case to go on.

EPULIS OF UPPER JAW.

He also exhibited an epulis of the upper jaw removed from a female. The growth, when it first made its appearance, resembled, by all accounts, a collection of sprouting granulations, due, as the patient believed, to the irritation of wearing a badly fitted set of teeth. In the course of three months it grew to a considerable size and became pedunculated. It was removed in the usual way by the saw and gouge, the attendant hæmorrhage being controlled by the persulphate of iron. The tumor was examined microscopically, and no traces of malignancy were found, notwithstanding that the gross appearances of the mass were at least suspicious.

INTERESTING EXPERIMENTS WITH LIGATURES.

Dr. B. Howard exhibited three specimens of ligation of the carotid arteries in the sheep, by different ligatures and in different manners, and made, in connection therewith, the following remarks:

A patient came to me with an axillary aneurism, and as immediate compression was, under the circumstances, impracticable, I thought of no other method of treatment save that of ligation of the subclavian. The condition of the artery, I apprehended, would not allow of ligation in the ordinary manner, by the silk ligature, and I thought if ligation were to be performed at all, it must be by the metallic ligature. We know that it is as generally accepted as taught, that the metallic ligature takes up its residence quietly wherever it is placed. Before proceeding, however, to perform such an operation, I thought it would be better to confirm these teachings first by experiment.

I accordingly obtained a very strong sheep, and applied a silver-wire ligature to the common carotid, and fastened it by twisting it very tightly. Fifty-six days afterwards, I cut down through the cica-

trix, and found that the collateral circulation which was established was very complete, and that the capillary circulation was not great; so that by making the section, which was, by the by, a vivisection, there was very little hæmorrhage. On coming down to the point of ligation, I was very much astonished to find what appeared to be a good-sized aneurism. I concluded, although I could detect no pulsation, that it was a dissecting aneurism; the ligature having perhaps caused ulceration of the middle and internal coats of the vessel. I removed it, and on section I was rather surprised to find what you here see—that this sac was an abscess full of inspissated pus, the pus having been in larger quantity than when I removed the tumor, as is manifested by the plications of the pyogenic membrane. It occupied a space of about four lines on either side of ligature, beyond which points the plugs were intact for about seven lines. In the centre of this abscess lay this ligature, with the middle and lining coats of the artery completely sloughed away and detached.

Here is another specimen removed from a pretty strong sheep. I applied a leaden ligature this time, and had it rather large, in order to avoid its cutting through. I tied it tightly, and, apprehensive that the sharp twisted ends might possibly produce some mechanical irritation, I sought to avoid it by securing the ends with perforated shot, they then being cut off smoothly. Twenty-six days afterwards, I cut down through the cicatrix, when instantly a pellet of pus appeared in the incision, as if propelled from behind. I made another incision, when the ligature and shot immediately followed it. As I proceeded towards the original site of the ligation, the hæmorrhage was exceedingly great—almost equal to that produced by dissecting through erectile tissue. I ligated above and below, and then removed this portion with the abscess which I present. There had been a good deal of inflammation around the artery, and there was considerable fibrinous material effused in the neighborhood. When preparing this specimen, I came to a point which I thought was no part of the tumor, but was misled; for, by continued clipping with a scissors, I came down to a part which was exceedingly dense, and, cutting that, a little opening was revealed, through which a piece of whalebone has been passed, and through which the ligature had ulcerated its way to the surface. On making a longitudinal section of this artery, I found it perfectly occluded, and well plugged on its cardiac and distal aspect. Between the proximal end of the distal plug and the distal end of the cardiac plug, was apparently an abscess containing about a drachm and a half of sero-purulent fluid; otherwise, the clot was perfect. The points of interest in this specimen are the great amount of irritation and inflammatory action that occurred about this metallic ligature, and that through the consequent excessive deposit of fibrine the ligature, shot and all, had worked its way, arriving nearly at the cicatrix of the integument.

I imagined that perhaps the kind of ligature was not the only consideration which should claim attention, and I obtained another sheep, to the common carotid of which I applied a silver-wire ligature, tying it incompletely after the manner of the silk ligature; but I was very careful to tie it loosely. I tied it tight enough only to diminish the canal of the artery to a considerable degree, but avoided, as nearly as I could judge, a complete closure.

On cutting down afterwards upon the cicatrix, I could scarcely discover whereabouts the ligature had been applied, so small was the amount of irritation it had produced. The plug in this case was more perfect than in either of the preceding cases. There was no abscess, the fibrinous deposit being just sufficient to cover the ligature. There was, on making the section, just a drop of something in which my friend Dr. Rogers, who has examined several specimens for me, thought he found one or two globules of a doubtful nature. At all events, the inflammatory action was exceedingly slight, only enough to be serviceable. The result, so far as occlusion, extent, and firmness of the plug are concerned, is very much better than in either of the other cases.

I am very unwilling, at present, to make any deductions from these experiments. They form only a small part of a series which I have in progress, each with a different ligature applied in a different manner. So far as these experiments go, other things being equal, it seems to be demonstrated, 1st, *that the metallic ligature does not always reside quietly where it is placed.* The last experiment demonstrates, 2d, *that it is not always necessary for complete occlusion of the artery to tie the ligature so tightly as to divide the middle and internal coats.* 3d. The last experiment is very suggestive, that a silver-wire ligature applied so loosely as to produce no lesion of the artery, nor even to completely arrest the circulation, may suffice for the cure of aneurism, when an ordinary ligature would be rendered inexpedient by the condition of the arterial coats.

Dr. Hamilton thought that such experiments as those detailed by Dr. Howard were particularly called for at this time. A great many trials, it is true, had been made with the ligature, but none as yet to test the relative value of the different kinds, more especially of the metallic. It was not strictly correct that the plan of applying the ligature for rupture of the middle and internal coats was absolutely necessary to success, as there were instances in which the old flat ligature accomplished occlusion without any such injury to the interior of the vessel. He was, however, much interested in knowing whether the metallic ligature had the additional advantage which was usually claimed for it over the silk. He was not fully convinced as to how much the sloughing was due to the different kinds of ligature, and to the different means that were taken in tying them to guard against undue irritation. He expressed a hope that the doctor would leave the points of his ligatures, in future experiments, entirely without the wound.

Dr. Bozeman, by invitation, referred to a case in which a ligature was applied, as in the third experiment of Dr. Howard, upon a human subject About three months ago he was called upon to apply a ligature to the carotid for aneurism of the temporo-maxillary artery. The ligature was applied with the same view as in the experiment referred to, and tied precisely as Dr. Howard had applied his, the idea being to effect *complete apposition* without rupture of the internal coats of the artery. The wound was closed in the ordinary way, and there was union by the first intention.

In answer to a question from Dr. Hamilton, he stated that he attributed the small amount of irritation which followed not so much to the ligature as to the manner in which it had been applied.

In this connection he referred to some experiments upon dogs which had been performed some forty years ago by Dr. Levert, of Mobile. Twelve or fifteen ligations had been performed upon the carotid—silver, gold, leaden, silk, grass, and hair ligatures had been used. He thought that in every instance in which the metallic ligatures were used they had become entirely encysted, there having been not a single instance of separation, and the occluded portions of the artery having been in from three to six months reduced to a cord.

Dr. Howard wished to state that experiment No. 3 differed essentially from the case related by Dr. Bozeman in this, that the canal was only diminished, not closed, as in the patient referred to.

Dr. Post thought that it had been the general impression among surgeons, that since the small ligatures came into use, and were so tied as to rupture the internal and middle coats, there was less danger than formerly from secondary hæmorrhage. The idea was to court union of the ruptured surfaces of the coats before the ligature should have a chance to ulcerate through.

Dr. Howard remarked that this principle was true with regard to the divided ends of arteries as in stumps, but when the ligatures were applied in the continuity of the vessel, as in the treatment for aneurism, they were liable to ulcerate their way prematurely through, and give rise to subsequent hæmorrhage.

Dr. Markoe thought that two surgical questions were involved in these experiments—the one had reference to the occlusion of the artery and the coming away of the ligature, the other to the obliteration of the vessel and allowing the ligature to become encysted. In the former case it seemed necessary that the process should be a rapid one by the rupture of the coats, while in the latter it was no question of time whatever, all that seemed necessary being the approximation of the opposed internal coats, leaving the obliteration to go on gradually.

Dr. Peaslee considered that the degree of tightness of the ligature was the question at the very foundation of the inquiry. It had long ago been settled by Dr. Knight, of New Haven, that an artery like the femoral could be occluded by digital compression kept up continuously for forty-eight hours. This, of course, proved that rupture of the arterial coats was not absolutely necessary to secure such an end. He believed that the degree of tightness of the ligatures alone produced the slough, and it mattered not what kind of material composed the thread, the silver wire being no more innocuous in that respect than the silk cord.

Dr. Sands, in this connection, referred to an operation performed by one of the surgeons of the New York Hospital. The case was one of popliteal aneurism, for which the femoral artery was to be ligated. The vessel was exposed in the usual way, when the thread was passed around it, and the ends passed through two perforations of the skin apart from the original incision, and tied over a roll of lint. The wound was then closed. He did not remember the details of the subsequent treatment, but he knew that very soon after the operation the patient had pretty severe inflammation, that the pressure had to be let up, that the pulsation returned in the tumor, and that the final result was the death of the patient from diffuse cellular inflammation.

In reply to a question by Dr. Howard, if Dr. Bozeman or any member present was aware of any record of the same kind of experiments as those presented, Dr. Bozeman replied he was not aware of any except those he had stated.

Dr. Markoe referred to a case of ligation of subclavian for aneurism reported by Mr. Porter, of London. The ligature was tied over a probe outside of the wound. At the end of fifty-six hours the patient was doing well.

The Society then adjourned.

Dr. Guillan, who was lately called in by Napoleon, declined any fee, saying that "the honor was sufficient for him." However, $2,000 were sent to him; but he made a present of the whole amount to the Academy of Medicine.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 6, 1867.

Dr. Alfred C. Post, President, in the Chair.

STATISTICAL MEDICINE.

Dr. Thoms read a paper upon the above subject, accompanied with a large number of diagrams, plans of inquiry, etc., which, as compilations, exhibited no little care and labor. He dwelt at length upon the representative value of figures as expressive of *exact* knowledge, and urged the necessity of care in the collection of our individual facts. These became important when grouped together, particularly since statistics were supposed to advance from facts to conclusions. The statements of a general observer were not of course entitled to as much credence as those of him who was prepared to corroborate every assertion with a fact ready at hand.

He thought that the subject was really more important than generally supposed, as honestly compiled statistics constituted the very foundation of science, and that every figure was endowed with a certain power of its own, even more significant than a printed page. The doctor also insisted that the study, although at first somewhat barren of interest, led us into correct habits of thought, and taught a proper discrimination in regard to the relative bearing of one fact upon another.

Dr. Bibbins, as indicative of the importance attached to the subject by "the Medical Society of the State of New York," referred to the terms of "the Brinsmade Prize," which at the last session of the Society was awarded to Dr. Franklin Hough. This called for a plan adapted for the tabulation of hospital reports, records of practice, etc. He could not but compliment Dr. Thoms upon his efforts to awaken the profession to the importance of the subject, appreciated perhaps only by those who were called upon to tabulate a great many facts, whose value was chiefly numerical. The obstetrical wards of any of our large hospitals furnished an example of the necessity of properly arranged tables, by suggesting to the investigator "what to observe." These tables, as economizers of labor, would prove a virtual boon to the profession, particularly to that portion, who, from the pressure of private practice and public duties, were compelled to note their facts on the instant. In London this was reduced to a system. He remembered, too, having admired several years ago, certain tables prepared in France. He was well aware that in the hospitals the young men would be likely to oppose the innovation, but when convinced of its labor-saving and time-economizing capacity, they would gladly second the endeavors of their superiors to test the measure.

He would also call attention to the importance attached by all readers of the secular papers to the data published by the Health Board. Dr. B. then concluded with a tribute to the author of the paper, as being entitled to congratulation for having presented the subject in so practical a form.

Dr. Herzog, while appreciating the efforts of Dr. Thoms, could not but regret that he had omitted from his plan all reference to condition of the soil and atmospheric influences. He deemed no plan perfect which did not provide for such observation, and would embrace every opportunity to urge upon his brethren the necessity of this, especially in the study of zymotic diseases.

Dr. Harris remarked upon the significant value of natural phenomena, and alluded to the labors of Pettenkoffer. He also referred to the very exhaustive manner in which the subject of moisture in the soil had been studied at Munich and Berlin, but as a whole, he

thought that temperature changes did not exert as much influence as was generally supposed.

He agreed with Dr. Thoms, that we should accurately state and analyze our facts, and concluded with some remarks upon the advantages to be gained by a greater attention to detail in the filling up of the death certificates, according to the form prescribed by the Health Board. He thought that the chief obstacle to accurate observation in these cases consisted in not appreciating the relationship between the disease and the sequelæ. Not phthisis, for instance, but pneumonia, an intercurrent complication, might terminate the life of the patient. Bright's disease of the kidneys and diphtheria might destroy, while the exanthematous poison was still in force.

KINGSLEY'S PORTABLE GAS BLOW-PIPE.

DR. POST exhibited a blow-pipe, invented by Prof. Norman W. Kingsley, of the New York College of Dentistry, which possessed the advantage of being worked by a thumb-pipe regulating the supply of gas and the volume of the flame. It was also capable of turning the flame in any direction, while one hand was free to control the object held; the flexible tube which constituted a part of the apparatus could be attached to any gas-pipe or burner, while the current of air was supplied by the mouth. a bellows, or in fact any power for such purpose.

DR. POST regarded the invention as especially serviecable in heating cauteries, in which case a small flame can be directed upon a given point of the metal employed.

In reply to a query of Dr. Budd's, concerning the relative merits of this apparatus and the ordinary blast-lamp, he was of opinion that the former had the advantages of simplicity, convenience, and a greater range of application.

A TRIBUTE TO THE MEMORY OF THE HEROES OF THE U. S. ARMY AND NAVY MEDICAL DEPARTMENTS.

DR. HARRIS prefaced the following resolutions with a tribute to the zeal and self-forgetfulness of the surgeons of the army and navy during the prevalence of the cholera and yellow fever epidemics.

Resolved, That this Academy view with peculiar satisfaction the honorable record of constant and heroic devotion to professional duty by the medical officers in the U. S. Army and Navy at all the stations where yellow fever prevailed during the present season.

Resolved, That to the memory of the medical officers and other physicians who have sacrificed their lives at posts of duty in the infected districts, this Academy hereby orders the names of these, our lamented brethren, to be publicly read before it at its anniversary meeting, to the end that the same may be entered upon the records in connection with these resolutions.

Resolved, That these resolutions be published in the medical journals of this city. Carried.

A GOVERNMENTAL INQUIRY INTO THE CAUSES OF THE LATE YELLOW FEVER EPIDEMIC.

DR. HERZOG presented the following, with the request that they be tabled until the next session of the Academy, since the lateness of the hour precluded discussion.

Whereas, From the earliest history of the country, the maritime regions of the Southern States have been visited by epidemic yellow fever, which on some occasions has been as destructive to life and to commerce as any epidemic recorded in history, and

Whereas, The essential nature of this disease, the question of its endemic or epidemic character, the laws of its origin and propagation, and the measures proper for its prevention, have never been investigated by the methods of modern science, and

Whereas, The Scientific Commission for the investigation of Asiatic cholera, organized by the Bavarian Government, has attained such results in exact knowledge as have brought that disease in great degree under sanitary control. Therefore

Resolved, That the Academy of Medicine will use its influence and solicit that of similar scientific bodies in aid of the appropriation by Congress of a sufficient sum, and the appointment of a commission to consist of men qualified in every department of natural science involved in such inquiry, to whom this subject shall be referred for investigation and report.

The Academy then adjourned.

Correspondence.

THE QUESTION OF PRIORITY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—In your number of October 15th, Dr. W. E. Vermilye asks for the insertion of a "few words in relation to the question of priority between myself and Dr. Taylor, in relation to the construction and use of the short splint in hip diseases."

This subject was so completely settled by my first letter in the *Medical Times* of 1861, and reprinted in the RECORD of October 1, 1867, and the dates therein given, that I confess myself somewhat surprised at the remarks he makes.

He says, "If I understand the matter," thereby admitting the doubt whether he does understand it or not, "Dr. Sayre has raised a *false* issue, both in his letter of July, 1861, and in the one recently published."

It certainly is very remarkable that this false issue was not discovered for *seven years* either by Dr. Taylor or Dr. Vermilye, as it has been published extensively to the profession, and applied in public at Bellevue Hospital *with a cross-piece and joint at the top*, and with a *branch* to take the adhesive straps from the *inside* of the thigh, in December, 1860, some months before Dr. Taylor constructed his instrument, and which, he says in his paper, he showed to me in February, 1861.

The instrument is labelled "Sayre's" by the instrument-maker, in order to distinguish it from others. As this whole matter is, however, a mere question of dates, which Dr. Mason's letter settles so completely, I hope I shall be spared from again coming before the profession on this subject.

LEWIS A. SAYRE, M.D.

Since the above has been in type, Dr. Sayre has received the following note, which will speak for itself:

NOV. 18, 1867.

PROF. L. A. SAYRE.

Dear Sir—In answer to your inquiries I beg to state, that in December, 1860, I made a short splint for the Commissioners of Public Charities and Corrections. I also made one about that time, or before, I believe, for a poor patient of yours in the Tenth avenue, near 50th street, New York. I have no entry of the latter case in my books, as I did not charge for the splint. Both of these splints had a branch to take the plaster from the inside of the thigh, and also a short cross-piece to go partially around the pelvis, and connected with the splint by a ball and socket joint.

I should have written to you earlier, but it was necessary for me to see Dr. E. Mason, to be sure of the date

that these splints were made. You may perhaps remember that the doctor was your assistant in Bellevue Hospital in the fall of 1860.

I am very respectfully,
W. F. Ford.

THE WASHINGTON UNIVERSITY.

To the Editor of the Medical Record.

Sir—In your issue for this month there is a notice of Washington University, in which my name, by some means, has been printed C. L. Ford. I should probably not have noticed the error had not Dr. C. L. Ford, of Ann Arbor, Michigan, addressed a communication to Rev. Dr. Bond, President of the College, which would indicate that he thought the person alluded to was himself—since he is of the impression that the faculty has been but recently organized, and the College not yet in operation. Very respectfully, etc.,

A. J. Foard, M.D.,
Prof. Anatomy, and Dean Washington Univ.

47 Liberty st., cor. Lexington,
Baltimore, Nov. 26, 1867.

New Instruments.

DR. D. H. GOODWILLIE'S INHALER.

We present a description of a simple, safe, efficient, and economical apparatus for the administration of all

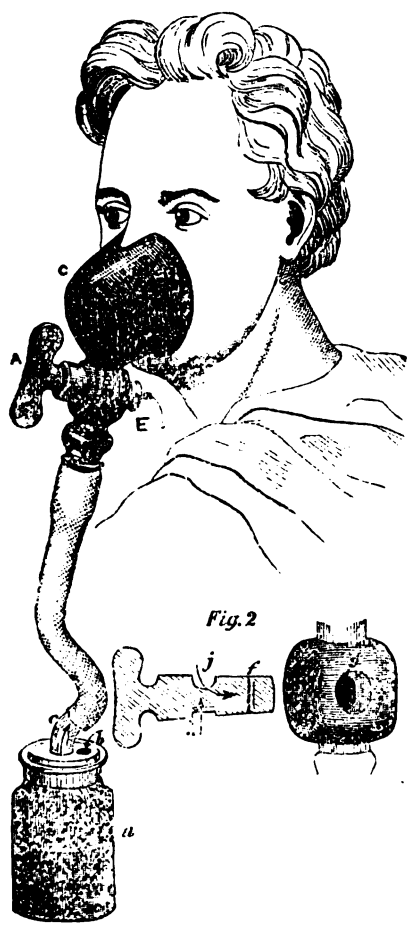

Fig. 2

the anæsthetics and medicated vapors, invented by Dr. D. H. Goodwillie of this city.

This inhaling apparatus, manufactured by Tiemann & Co. of this city, consists of a face piece (C), connected with it a faucet (A) which contains the inhalation-valve (Fig. 2, *h*) for the passage of the vapor, and exhalation-valve (*f*) for the escape of the expired breath, and a fresh air-passage (*g*), with an index to show the amount of vapor and air being inhaled at any time during the administration. The inhaler is connected by a flexible tube to the bottle (*a*) containing a sponge, and half filled with the anæsthetic fluid to be used. Air is admitted by a tube (*b*) to the centre of the sponge, to evaporize the fluid on the upper half of it during the inhalation. The inhalation-valve and air-passage are of the same caliber, and divided by the index into five parts. The revolution of the faucet over the inhalation-valve and air-passage controls the inhalation of vapor and air. Figure 1 on the index shows the minimum amount of vapor, and 4 the maximum amount. The fifth part is always fresh air. Revolving the faucet from 1 to 4 increases the vapor and decreases the air. 4 to 1, *vice versâ*. All the vapor can be shut off and fresh air admitted without removing the inhaler from the face. For example, let the faucet be revolved to 2 on the index, then two parts of vapor and three parts air are inhaled. The gradual inhalation accustoms the air-passages to the vapor, and thus produces less spasm of the epiglottis, coughing, struggling, and sickness, and narcotism is quietly produced and easily maintained. By this apparatus the administrator has full knowledge and control of the vapor inhaled. A great saving of chloroform or ether is effected, as the vapor from the bottle passes direct to the lungs, and is mixed with air at the will of the administrator by the faucet.

This apparatus can be applied to the inhalation of all the anæsthetics and medicated vapors.

Obituary.

PROFESSOR WORTHINGTON HOOKER, M.D.,

New Haven, Conn.

The profession throughout the country has been called upon to mourn the untimely removal by death of one of its most widely known, cherished, and active members. Engaged in the practice of his profession for a period of forty years, and winning by his literary talents a reputation in early professional life, he became identified with two generations. His life affords an illustration of what any physician can make himself by arduous labor and fidelity of purpose. Although practising the art which he loved so well up to his death, he always found time and opportunity to devote himself to the fascinations of literature, both within and beyond the pale of his profession. No one in our ranks has enjoyed a success in the circulation of publications greater than his. This is particularly the case with several minor works upon scientific matters, designed for schools and colleges, among which may be mentioned, "The Child's Book of Nature," and his "Physiology for Colleges and Schools." Both of these have been extensively adopted by the various institutions of learning throughout New England. His first work was entitled, "The Physician and Patient," and so well was it written, that he laid by it the foundation-stone for an enviable literary reputation. His contributions to the medical journals were varied, practical, and valuable, and on two different occasions he was awarded a prize for medical essays by the American Medical Association. He was everywhere distinguished for his affable and generous nature, and raised for himself hosts of friends whose hearts are now painfully sad over his departure.

Born in Springfield, Mass., in the year 1805, he was sixty-two years of age at the time of his death. He graduated at Yale in the class of 1825. In the same class were President North of Hamilton College, Governor Ford of Ohio, Chief Justice Thomas Slidell of the Supreme Court of Louisiana, Hons. George W. Woodruff, Thomas H. Bond, William B. Bristol, Abijah Catlin, and Dr. N. B. Ives. He commenced the study of medicine in the Harvard Medical School immediately after graduation, and, upon the conclusion of his studies, in 1828, he established himself in practice in Norwich, Conn., where he remained until 1852, when he left for New Haven to accept the Professorship of Theory and Practice in Yale College. He continued in connection with that institution until his death, distinguishing himself as a teacher and an advocate for the elevation of the standard of medical education. The interest which he took in this latter subject manifested itself in many praiseworthy efforts before the American Medical Association, and caused him to be looked to as one of the radical pioneers in the advancement of the interests of the brotherhood.

In 1830 he married Miss Mary Ingersoll, of Springfield, who died shortly before he left Norwich. Subsequently he united himself to a daughter of the late Governor Edwards, who survives him.

Added to his other graces was the exalted one of a consistent Christian, he being for many years a prominent and zealous member of the Congregational denomination, and an active worker in the Sunday-school department.

In his decease a vacant place is left in our ranks which cannot be easily filled, but he has left us an example by which all can profit, and we need hope for nothing better than that our last end may be like his. His eloquent tongue is silent, his accomplished pen is at rest, but his ennobling record lives after him, and his memory will be kept green by the thousands he has instructed and befriended.

A TREATISE ON THE CAUSE OF EXHAUSTED VITALITY, or Abuses of the Sexual Function. By E. P. MILLER, M.D., Physician to the Hygienic Institute and Turkish Baths, etc., etc. New York: J. A. Gray & Green, 1867.

Medical Items and News.

THE LATE PROF. ROBERT WATTS, M.D.— *Whereas*, it has pleased an All-wise Providence to take from the scene of his earthly labors one of the oldest and best beloved members of this Society, DR. ROBERT WATTS; therefore,

Resolved, That in the death of our late associate we deplore the loss of a sagacious physician, a genial companion, and a true friend.

Resolved, That in this Society, where for so many years he found the most grateful recreation from the labors of an arduous practice, we cannot cherish too warmly the memory of his ever-welcome presence.

Resolved, That to the profession, as well as to this Society and his many friends, the exalted character of Dr. Watts as a man, his ability and self-sacrificing devotion as a physician, and his noble qualities of heart, will ever make him an example worthy of emulation and regard.

Resolved, That a copy of these resolutions be transmitted to the family of the deceased, and that they be published in the medical journals of this city.

T. M. MARKOE, M.D., *President.*
FOSTER SWIFT, M.D., *Secretary.*

At a meeting of the Students of the College of Physicians and Surgeons, held in the Hall of the College, October 18, 1867, the following preamble and resolutions were adopted:

Whereas, We the Students of the College of Physicians and Surgeons, have heard with sincere regret of the death of our Professor of Anatomy, Dr. Robert Watts, and

Whereas, We ever found in him an able and efficient instructor, a true and sympathizing friend; therefore, be it

Resolved, That, while we would ever recognize the will of an All-wise Providence, we deplore the death of one so eminently qualified by rare mental attainments, and by the naturally pleasant traits of his character, for the position, the duties of which he so long and faithfully performed.

Resolved, That we tender our heartfelt sympathy to the family of the deceased, and would comfort them with the assurance that he has left behind him many endearing fruits of a useful and well-spent life.

Resolved, That as a tribute of respect to the memory of our late professor, we, as a class, attend his funeral and wear a badge of mourning for thirty days.

Resolved, That a copy of these resolutions be sent to the family, and also that they be published in two of the New York daily papers and in two of the leading medical journals of the United States.

FRANK W. ROCKWELL,
JOHN J. PRENDERGAST,
WILLARD PARKER, Jr., } *Committee.*

DR. CARTER, an eminent physician of Charlottesville, Va., died on Thursday, November 7, of apoplexy, in the seventy-sixth year of his age. Dr. Carter graduated in Philadelphia, in 1812, and settled in Charlottesville in 1824. He had been a practising physician for fifty-five years, and was beloved wherever known for his many amiable qualities.

A PREMIUM FOR AN ESSAY ON CROUP.—The Emperor Napoleon, having lost a nephew by croup, offers a premium of 12,000 francs for the best essay on that disease.

Poisoned by Myrbane.—An inquiry was held by Mr. John Humphreys, the Middlesex coroner, at the Black Horse tavern, Kingsland-road, into the death of the wife of a tradesman living at 64 Kingsland-road. Her name was Elizabeth Masham, aged sixty-four years. On the 27th ult. she went on a visit to Mr. and Mrs. Kipple. While there she was seized with spasms, and went to a cupboard, and drank what she thought was brandy. She had made a mistake, and drank some myrbane. Mrs. Kipple said that the smell was sickening. Mr. John Masham stated that when he found that his wife had been poisoned he placed a quarter of a teaspoonful of the liquid into his mouth. His face began to glow, and his sight became confused. He then spat it out. For three days after he was dizzy. Dr. Hoskins proved that the deceased expired on Wednesday, from the effects of poisoning by myrbane. She was insensible for three days before her death. The coroner said that the present was the third case of myrbane poisoning on record. Both the other cases had come under his notice. One of them was that of a young man, who swallowed some of the poison while sucking a syphon to make it run. That occurred at a chemical factory. The other death arose from a man spilling a carboy filled with it over his clothes. In order to dry them he lay down in front of a fire, and the poisonous vapor killed him. He was found dead. Myrbane was quite a new poison, and it had been accidentally discovered by a chemist, who was making the magenta color out of coal-tar. It was used to scent oils and to give a flavor to cakes. Cheap pastrycooks bought it at 6s. to 8s. a pound, and used it instead of bitter almonds, which cost 12s. a pound. Three drops of it in a pound cake would not do damage. The jury returned a verdict, "That the deceased was accidentally poisoned by myrbane."—*London News.*

Dr. Karl Thiersch, Professor at Erlangen, son-in-law of the celebrated chemist, J. von Liebig, has accepted the call as Professor of Surgery and Director of the Surgical Clinic at Leipsic, in the place of Gunther, deceased.

Professor Lieberkuhn has been called to the chair of Anatomy at the University of Marburg.

Dr. Ignaz Ritter v. Nadherny died in Vienna on the 5th of August, in the eightieth year of his age, after a life of active and earnest labor devoted to the honor of his profession and the good of his fellow men. He commenced public life more than fifty years ago as Professor of Medical Jurisprudence in Prague, was afterwards elevated to various positions of official trust in Bohemia, and finally made chief of the medical branch of the department of Public Instruction. His labors for the public hygiene of Bohemia were stupendous; his efforts on behalf of the charitable institutions of Prague unremitting; while two generations of physicians looked up with reverential love and awe to their patriarch and nestor, Nadherny. He was untiring in his labors of love for a suffering humanity; no work was too hard, no sacrifice too great for him. Three monarchs of Europe recognized his services by elevating him to the rank of Knight, and conferring on him titles, decorations, and testimonials of every description; while in the hearts of the people he has built himself a monument of everlasting gratitude.—*Allgemeine Wiener Zeitung.*

Dr. Edmund Rose of Berlin succeeds Billroth as Professor of Surgery and Director of the Surgical Clinic at Zurich, Switzerland.

The Treatment of Infantile Paralysis.—At the regular meeting of the Paris Academy of Medicine held on the 17th of September, M. Bouvier presented from Dr. C. F. Taylor, of New York, a work entitled *Infantile Paralysis and its Attendant Deformities.* At the same time he showed to the Academy two forms of apparatus, from Dr. Taylor, one for the treatment of Pott's disease and the other for coxalgia.

"The apparatus which I have the honor to present to the Academy," said M. Bouvier, "has been on exhibition in the American section of the Exposition. It differs essentially, as may be seen, from those which are ordinarily employed in the treatment of Pott's disease. It combines all the advantages of horizontal position, while, at the same time, it gives the patient exercise and fresh air. With this apparatus Dr. Taylor endeavors to protect the diseased vertebræ, as is done in the dorsal decubitus without the aid of the instrument. Like a bed securely attached to the dorsal region, the instrument exercises on the vertebral column an equable pressure, as would result from the patient's weight when in bed. This force is uniformly anteroposterior.

"The apparatus is a simple lever, which raises the superior part of the vertebral column, by using the transverse processes as the fulcrum; so that, whilst pressure on the articulations of the transverse processes is safely increased, the pressure on the bodies of the diseased vertebræ is considerably diminished. The instrument is hinged, and acts like a supplementary vertebral column. Its arrangement enables one to appreciate exactly and to modify the degree of force employed, and to render the treatment constantly and regularly progressive. It also assists the contractions of the spinal muscles. The ability of the patient to be in the open air, while the seat of disease is protected against all shock—this constitutes the superiority of this mode of treatment.

"The other apparatus is designed for counter-extension in coxalgia. The idea of counter-extension originated with Dr. Davis (of New York), but this instrument is nevertheless the invention of Dr. Taylor. It consists, 1st, of a belt, provided with two straps, which embrace the perineum, producing extension from above; 2d, of a long extensible splint, received under the foot by a strap, which is a continuation of the adhesive straps applied to each side of the thigh and around the limb; this strap produces counter-extension.

"Elongation is accomplished by means of a lateral screw. Not only the muscular tonicity is overcome, and the articulation preserved from pressure or shock, but during locomotion the weight of the body is sustained by the instrument, because the body rests on the straps which embrace the perineum.

"The result of Dr. Taylor's experience shows that when the tonicity of the muscles of the hip is completely overcome, and the parts are guarded from pressure and shock, locomotion is not only free from danger, but, on the contrary, very advantageous, because the patient can thus profit by the potent measures which hygiene places at our disposal."—*Gaz. des Hôpitaux.*

The Present Raid on the Uterus.—The following extract from the address of Dr. W. D. Buck, before the New Hampshire Medical Society, is copied from the St. Louis *Medical Reporter:* "The uterus is a harmless, inoffensive little organ, stowed away in a quiet little place. Simply a muscular organ, having no function to perform save at certain periods of life, but furnishing a capital field for surgical operations, and is now-a-days subject to all sorts of barbarity from surgeons anxious for notoriety. Had dame Nature foreseen this, she would have made it iron-clad. What with burning and cauterizing, cutting and slashing, and split-

ting, and skewering, and pessarying, the old fashioned womb will cease to exist, except in history. The Transactions of the National Medical Association for 1864 has figured 123 different kinds of pessaries, embracing every variety, from a simple plug to a patent threshing machine, which can only be worn with the largest hoops. They look like the drawings of turbine water-wheels, or a leaf from a work on Entomology. Pessaries, I suppose, are sometimes useful, but there are more than there is necessity for. I do think this filling up the vagina with such traps, making a Chinese toy-shop of it, is outrageous. Hippocrates said he never would recommend a pessary to procure abortion, nay, he swore he never would. Were he alive now he would never recommend one at all. If there were fewer abortions there would be fewer pessaries, and if there were fewer pessaries there would be fewer abortions. Our grandmothers never knew they had wombs, only as they were reminded of it by a healthy fœtus; which, by the by, they always held on to. Now-a-days even our young women must have their wombs shoved up, and if a baby accidentally gets in by the side of the machinery, and finds a lodgment in the uterus, it may, perchance, have a knitting-needle stuck in its eyes before it has any. It is the easiest thing in the world to introduce a speculum, and pretend to discover ulceration of the os, and subject a patient to this revolting manipulation once or twice a week, when there is, in fact, nothing the matter. By some practitioners, all diseases which occur in the female are attributed to the uterus. In this class are especially to be included all such as make of the abnormal conditions of the uterus a specialty."

A Magnetic Bullet Probe.—Mr. Sylvande Wilde has invented an instrument for extracting bullets in wounds, which has been aptly called a sensitive artificial finger, for its action depends on the actual presence of the bullet sought for. It consists of two insulated steel wires, which are connected with an electro-magnet and a bell, so arranged that the electric circuit will pass through the two wires whenever they are connected by contact with the same piece of metal, which will form a part of the conductor. The points of the probe are sheathed in a sliding-tube when introduced into the wound, and are not uncovered until the supposed bullet is felt. The forceps have curved points, and are not pallets or spoons. When the ends of the probe are uncovered, on touching the bullet, the latter completes an electric circuit, which sets in motion a magnet, and by its attraction compels the forceps to grasp the bullet; it is then ready to be drawn out.

Humoral Pathology again in the Ascendant.—It is a remarkable fact that the humoral theory in pathology, which dates back as far as Hippocrates, and which was of course founded only upon bold speculation, is now emerging by the aid of science from the almost universal contempt into which it had sunk, and becoming a received dogma. We now depend upon the different emunctories, and do not attempt to extinguish the disease at the hazard of life. In a word, we "soothe and sustain," as Dr. Flint with a beautiful conciseness expresses it, while the process of purification is in progress. As defendants of the expectant school, we now fortify the system to prepare it against the assaults of an ill-conditioned militia mustered in for an emergency. —*Private Letter.*

The Female Doctor Question Abroad.—Mme. Sourkof has just received the degree of Doctor of Medicine from the University of Zurich. She is Russian by birth, and studied at St. Petersburg with great credit until the Russian government forbade the conferring of degrees in medicine upon women.

An Extensive Hospital.—An exchange states, on the authority of Dr. Nathan R. Smith, of Baltimore, Md., who has recently returned from Europe, that the city of Milan can boast of the most magnificent hospital in all Europe. It contains 2,500 beds.

The Colors of Soap-Bubbles.—At the late meeting of the British Association for the Advancement of Science, Sir David Brewster read a paper on this subject, from which it appears that he had been led to make some new investigations as to the cause of colors of soap-bubbles, after he had repeated the beautiful experiments of Professor Plateau, "On the Equilibrium of a Liquid Mass without Gravity." In these cases the colors of soap-bubbles were presented to him upon soap-films, plane, convex and concave; but the changes of form which they underwent, and their motions upon the film itself, were incompatible with the common theory of their formation. After describing various phenomena emitted by the ordinary soap-bubble, and also with the bubble having its film toughened by a mixture of glycerine, Sir David remarked that his experiments were sufficient to establish the almost incredible truth that the colors of the soap-bubble are not produced by the thickness of the film itself, but by the secretion from it of a new substance flowing over the film and expanding, under the influence of gravity and molecular forces, into colored groups of various shapes, and returning spontaneously, when not returned forcibly, into the parent films.

At the conclusion of the paper, Sir William Thomson remarked that the mechanical questions involved in the seemingly simple operation of blowing soap bubbles were the greatest enigmas to scientific men. The extraordinary expansion and adhesion combined in the vapor spheres were well worthy of the fullest investigation.

Ophthalmic and Aural Medicine and Surgery.—John P. Garrish, M.D., will deliver his introductory to a course of lectures on Ophthalmic and Aural Medicine and Surgery, at the Cosmopolitan Hospital rooms, No. 65 West Thirty-fourth street, corner of Broadway, on Thursday evening, December 5th, at eight o'clock. The profession and students of medicine are invited to attend.

Birth and Death-Rate of the World.—Statisticians have calculated that if the population of the world amounts to between twelve hundred and thirteen hundred million persons, the number of deaths in a year would be about thirty-two millions. Assuming the correctness of this calculation, the deaths each day would be nearly 88,000; 3,600 per hour; 60 per minute; and thus every second would carry into eternity one human life from one part of the world or another. But reproduction asserts its superior power; for, on calculating the probable annual births on the globe, the result shows that whereas 60 persons die per minute, 70 children are born, and thus the increase of the population is kept up.—*Lancet.*

The Sapphires of Montana.—The Montana people are congratulating themselves over the discovery of genuine sapphires in that territory. The precious stones found on El Dorado Bar are familiarly known in that locality by the name of "Collins' diamonds," and are said to be quite plentiful and easily procured.

New York Eye and Ear Infirmary.—Dr. F. J. Bumstead has resigned his position as Surgeon to this Institution.

Original Communications.

EXPERIMENTS ILLUSTRATING THE DIRECT ACTION OF HYDROCYANIC ACID UPON THE MEDULLA OBLONGATA.

By JOSEPH JONES, M.D.

PROFESSOR OF PHYSIOLOGY AND PATHOLOGY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF NASHVILLE, AND HEALTH OFFICER, CITY OF NASHVILLE.

SUMMARY.—*Experiment* 1. *Effects of Prussic Acid administered by the Mouth.—Experiment* 2. *Brain of Alligator exposed, and Prussic Acid applied.—Experiment* 3. *Prussic Acid applied to Spinal Cord in tail of young Alligator.—Experiment* 4. *Prussic Acid applied to Spinal Cord, midway between Anterior and Posterior Extremities —Experiment* 5. *Poison applied to Spinal Marrow, midway between Anterior Extremities and base of Brain —Experiments* 6, 7, 8, *and* 9. *Prussic Acid applied to Medulla Oblongata.*

THE following ten experiments were performed in the month of April, 1862, at Montevideo, Liberty Co., Georgia.

A solution of prussic acid was freshly prepared, of a strength equal to that of the fresh Acidum Hydrocyanicum Dilutum, U. S. P.

For these experiments I selected ten young alligators (Alligator Mississippiensis) of the same age, and from the same nest.

Effects of Prussic Acid administered by the Mouth: Experiment 1.—Poured a solution of prussic acid, in amount about f ʒ ss., down the mouth and throat of a small young alligator. The reptile was only six inches in length, and had not left the egg-shell more than a week or ten days.

In three and a half minutes the alligator manifested signs of the action of the poison, in its staggering gait and convulsive movements; in twelve minutes, gaping and struggling violently, with spasmodic movements of the muscles; in fifteen minutes, breathes only occasionally (once every two or three minutes), and then in a spasmodic manner, lies indifferently upon the back or belly, and cannot walk; sixteen minutes after the first application of the poison, and one minute after the last observation, all motions appear to have ceased; when thrown into cold water, however, it appears to be aroused by the shock, and makes several attempts to swim and turn on its side; these motions ceased in a few minutes, and when turned over on its back in the water, it remained so, whilst an alligator whose cerebrum had been exposed, and touched with the same solution of prussic acid, remained vigorous and strong.

Twenty-six minutes (ten minutes after the preceding observation), lies as if dead, without any motion, except, every two or three minutes, a spasmodic, feeble, respiratory effort; mechanical stimuli produced but a slight tremulous motion of the muscles, whilst irritation of the muscles of the alligator whose cerebrum had been exposed and treated with hydrocyanic acid, induced vigorous respiratory motions; in thirty minutes (four minutes after the last observation), all external signs of life have vanished, and the animal appears to be dead.

Thirty minutes after the application of the poison, the thorax was opened and the heart exposed; auricles and ventricles greatly distended with blood, beating slowly and spasmodically forty times per minute; fifty-two minutes (twenty-two minutes after the last observation), action of heart, twenty-six per minute; one hundred and twelve minutes (sixty minutes after the last observation), action of heart twenty-six per minute; one hundred and eighty minutes (sixty-eight minutes after last observation), no signs of life in the muscular system; mechanical stimuli fail to produce contractions; heart still acts in a slow, spasmodic manner; the blood presents a brownish purplish color; auricles and ventricle still engorged with dark blood; action of heart, twenty per minute.

Two hundred and fifty-eight minutes (seventy-eight minutes after the last observation), pulsations of the heart still continue, they are however s ower and more irregular and spasmodic, the *rhythm* of its action has been destroyed; the auricles act continuously about ten times per minute, the ventricle not so often. The action of the heart continued to grow slower and slower until it finally ceased. The exact time was not noted.

Prussic Acid applied to Brain of Alligator. Experiment 2.—Removed the superior plate of the cranium of a small alligator (six inches in length), and exposed the superior surface of the cerebrum without wounding the large veins and arteries. The membranes were carefully removed from both hemispheres, so as not to injure the great central vessels running between the hemispheres and the cerebellum.

The surface thus exposed was moistened with the solution of prussic acid.

Four minutes after the direct application of the poison to the surface of the cerebrum, no signs of the action of the hydrocyanic acid; the surface of the brain was wounded, and the poison again applied. In eleven minutes (seven minutes after the last observation), the effects are beginning to be manifest, in a decrease of activity and life in the muscular motions: the reptile is still able to crawl about, and to make the sounds usually emitted by young alligators. The blood oozing from the wounded surface of the brain presents a brilliant crimson color.

In fifteen minutes (four minutes after the last observation), motions spasmodic, gasps for breath, and emits quick, spasmodic sounds, like an imperfect bark; these spasmodic motions ceased in a few moments. The reptile crawled off and attempted to bite the finger when placed before its head, and when thrown into cold water it swam rapidly. The effects of the poison appear to be due chiefly to its absorption by the blood-vessels of the brain, and its distribution to other portions of the nervous system, and not to a direct action upon the nervous structures constituting the cerebrum.

The poison was again applied to the exposed surface of the cerebrum, and its structures were again injured so that the poison might come in immediate contact with the nervous elements. Twenty-four minutes after the first application, still able to swim, but evidently losing power: the respiration is slow, spasmodic, and irregular. In the last application, the nervous structures were more extensively injured, and the poison more effectually applied.

The forces gradually declined, and thirty-six minutes after the first application (twelve minutes after the last observation) the alligator has so far lost voluntary motion that, when thrown into cold water, it remains indifferently upon the back or belly, as it may be placed; still breathing, but the respiration is very slow and spasmodic.

The heart was next exposed; the act of cutting through the muscles to expose the heart caused contractions of the various muscles of the thorax and fore-

limbs; action of heart thirty-eight per minute, more regular and active than the heart of the alligator in the preceding experiment, auricles and ventricle filled with crimson blood; forty-two minutes, action of heart thirty-eight.

One hundred and sixty-eight minutes after first application of poison to cerebrum (one hundred and twenty-six minutes after last observation), the reptile has greatly recovered, and is attempting to walk; heart beating with considerable regularity and force.

The remaining coverings of the superior and posterior parts of the cerebrum, especially those portions of the dura mater and arachnoid which dip down between the hemispheres, and between the cerebrum and cerebellum, were removed. Considerable hæmorrhage ensued from the large blood-vessels; this was wiped carefully away, and the prussic acid again applied to the surface of the brain, reaching the cerebellum (necessarily from the anatomical relations of the membranes removed and the large blood-vessels cut), and perhaps also in small quantities the medulla oblongata and spinal cord.

The poison acted almost immediately, producing tetanic spasms, followed by cessation of respiration and loss of muscular power.

One hundred and seventy-eight minutes after the first application, and ten minutes after the last, the action of the heart was twenty-four per minute; two hundred and fifty-eight minutes (ninety minutes after the last observation), muscles still respond slightly to mechanical stimuli; heart still acts ten times per minute spasmodically. Since the loss of blood from the blood-vessels of the brain, the heart is not so filled with blood, and continued to diminish in the size and in the frequency of action, until it ceased in about an hour after the last observation. The precise time of the cessation of its action was not noted.

Prussic Acid applied to Spinal Marrow. Experiment 3. — Exposed the spinal cord in the tail of a young alligator for half an inch, commencing just below the junction of the hind legs, and applied the solution of prussic acid used in the preceding experiments to the surface of the spinal cord; immediate contraction of the muscles and cries of pain followed the application; these, however, soon subsided and the animal became quiet. No special effect was produced upon the respiratory acts, except to render them fuller and somewhat labored.

Two minutes after the poison was again applied and produced similar results—contractions and cries of pain, and full laborious respiration. As often as applied to the spinal cord, it produced these effects—they are, however, evidently becoming less marked. Eight minutes after the first application, when thrown into cold water, the reptile swims; ten minutes after (two minutes after last observation), spasmodic attempts at respiration, gapings of the mouth and throat, and spasmodic attempts to crawl; twenty-five minutes, limbs spasmed, muscular powers feeble, lies in partial stupor. In thirty minutes after the first application of the poison, all external signs of life are extinct; when the thorax was opened, however, a convulsive motion of the respiratory muscles ensued, inflating still farther the lungs. Heart acting regularly, contracted, and not engorged with blood; the absence of the usual large amount of blood in the cavities of the heart in poisoning with hydrocyanic acid, appears to be referable to the loss of blood which ensued from the tail, which was considerable. Action of heart, thirty-two per minute.

One hundred minutes after the first application of the poison the heart ceased to beat.

Prussic Acid applied to Spinal Marrow. Experiment 4. — Exposed the spinal cord of a young alligator midway between the anterior and posterior extremities, and applied prussic acid of the same strength as in the preceding experiments; spasmodic contractions and motions of the muscles and limbs were almost immediately excited. The respiration still continued, notwithstanding several repetitions of the poison. Eighteen minutes after the application respiration still continues; twenty-two minutes, still breathes slowly, although the muscles respond but little to mechanical excitements; at the end of forty-two minutes all external signs of life were gone. Heart still acting fifty times per minute.

Prussic Acid applied to Spinal Marrow. Experiment 5. —Exposed the spinal cord of a young alligator, midway between the fore-legs and base of brain, and applied prussic acid—tetanic spasms of the voluntary muscles followed, without the arrest of respiration. Fifteen minutes after the application of the poison, still breathes and attempts to swim when thrown into water; swims with the hind, but not with the fore-legs, and appears to have lost much of the power of the fore-legs. In fifty-two minutes all external signs of life have become extinct. Heart exposed, still acting thirty-two times in the minute.

Prussic Acid applied to Brain and Medulla Oblongata. Experiment 6.—Exposed the cerebrum, cerebellum, medulla oblongata, and superior portion of the spinal cord of a young alligator (Alligator Mississippiensis)—considerable blood was lost during the removal of the walls of the cranium and vertebræ, the animal appeared exhausted, and the nervous muscular actions appeared to be influenced by the loss of blood and the violence inflicted upon the membranes of the brain and spinal cord; the motions of the animal were rendered somewhat irregular and spasmodic. A solution of prussic acid of the same strength as that employed in the preceding experiments, was applied to the nervous structures exposed, without however taking the precaution to wipe away the blood, which was continually oozing from the divided vessels. No immediate effect was produced, and eight minutes afterwards the alligator was still able to swim with precision and vigor when thrown into water. After removing the animal from the water, the nervous structures were carefully wiped dry, thus removing all the blood and water, and the poison was then applied immediately to the exposed surfaces. This last application appeared to have a more immediate and decided effect than the previous one, and in one minute spasms with convulsive cries were excited. Fifteen minutes after the first application, and seven minutes after the second application, respiration was irregular, not more than two or three times per minute, and mechanical stimuli caused but little effect upon the voluntary muscles—when thrown into the water, the animal lies indifferently upon the back or belly. In a few minutes more, all voluntary muscular motions ceased entirely. When the heart was exposed, it was beating regularly, and did not present the engorged appearance of the heart of the alligator into whose mouth and stomach the poison had been introduced (Ex. 1).

In the present case the action of the poison produced a powerful contraction of the respiratory muscles, and complete expulsion of the air contained in the lungs.

In one hundred and thirty-five minutes from the first application, the heart had ceased to beat; artificial respiration and inflation of the collapsed lungs restored the action of the heart. During the process of artificial respiration there was a partial restoration of the irritability of the muscles. At the end of two hundred and fifteen minutes all action in the heart had ceased. The more early extinction of the powers of the heart, in

this experiment than in the first, was due in great measure to the loss of blood.

Prussic Acid applied to Medulla Oblongata. Experiment 7.—Exposed the brain and medulla oblongata of a small alligator, and after wiping off the blood carefully applied the solution of prussic acid to these parts—in less than a minute, in fact almost immediately, violent convulsive movements were excited, violent expiration of air from the lungs, and death in a few moments. The lungs remained permanently collapsed and the respiratory muscles contracted. The collapsed contracted appearance of the thorax and abdomen was in striking contrast to the inflated body of the alligator killed in the first experiment by the internal administration of the poison.

Thorax opened one hundred and twenty minutes after the application of the poison; heart had ceased to pulsate. Inflation of the lungs was followed by a renewal of the action of the heart. The cessation of the action of the heart, in the two last experiments, sooner than in the two first experiments, was due to the collapsed state of the lungs, and the greater loss of blood in the latter. In the two first experiments the lungs remained inflated, and there had not been any loss of blood in the first reptile experimented on, and in the second none for some time after the commencement of the experiment.

In the present (7th) experiment, the muscles responded to mechanical stimuli after the institution of artificial respiration. At the expiration of two hundred and ten minutes, all action in the heart had ceased. On account of the loss of blood, the heart presented a pale appearance, contracted, and with but little blood in its cavities.

Prussic Acid applied to Medulla Oblongata. Experiment 8.—Exposed the medulla oblongata of a small alligator, and applied directly to the nervous structures the solution of prussic acid; convulsions, suspension of respiration, and apparent death followed almost immediately.

The air was driven forcibly out of the lungs, and the respiratory and abdominal muscles remained contracted so as to present a contracted appearance of the chest and abdomen. The heart exposed one hundred and twenty minutes after the application of the poison, had ceased to beat; it contained little or no blood, and was pale and contracted. Inflation of the lungs restored its action. Two hundred and ten minutes after the application of the poison, the action of the heart had ceased.

Prussic Acid applied to Medulla Oblongata. Experiment 9.—Exposed the medulla oblongata of a young alligator and applied prussic acid—the effect was almost immediate; in one minute the respiration was arrested, and the respiratory muscles permanently contracted. The eyes winked, and the mouth gaped for some eight minutes, and even long after the eyes and mouth ceased to move of themselves, the eyes would wink, and the muscles of the jaw would contract when pinched, Thirty minutes after the action of the poison, the heart was exposed—lungs contracted, the act of cutting excited contractions in the respiratory muscles—heart acting forty-four times per minute regularly.

It is worthy of note in these experiments, that the lungs were collapsed, and the respiratory muscles forcibly and permanently contracted only when the poison was applied to the medulla oblongata.

Prussic Acid applied to Medulla Oblongata. Experiment 10.—Removed all the skin over the cranium and spinal column of a young alligator and applied prussic acid of the same strength as that used in the preceding experiment. At the end of seven minutes the reptile still shows signs of great activity, being able both to swim and walk; at the end of eighteen minutes after the application of the poison, although manifesting its effects in loss of power and irregular movements, still it swam with vigor and precision when thrown into water. The bony wall was then removed, the medulla oblongata exposed, and the poison applied directly to its surface; the effect was evident in a few seconds, and whilst there were no well marked tetanic spasms, still the respiration ceased, as well as all voluntary motions. When mechanical stimuli were applied, reflex actions of the extremities indicated the exis ence of nervous and muscular irritability.

Heart exposed ninety-five minutes afterwards; its action was a mere tremor.

From these experiments we conclude that prussic acid acts primarily, directly, and chiefly upon the medulla oblongata and spinal cord; and that its ability to produce sudden death is dependent upon its action upon the medulla oblongata.

Derangements in the relations of the medulla oblongata and spinal cord to the muscular system generally, and especially to the respiratory system, are the first phenomena manifested in the action of prussic acid.

When absorbed from a raw surface, or from the stomach and bowels, these phenomena are manifested, as well as upon the direct application of the poison to the medulla oblongata, but more slowly. In warm-blooded animals death takes place almost immediately after the administration or inhalation of the poison; still, when taken by the mouth, a sufficient time always elapses for the absorption of the poison and its distribution to the great nervous centres. As soon as the poison in the blood reaches the medulla oblongata and spinal cord, convulsive motions are excited, and if the impression be sufficiently intense there is an immediate arrest of the action of the ganglionic cells presiding over the respiratory process, and immediate death follows.

In the young alligator the cartilaginous walls of the cerebro-spinal nervous system can readily be removed by the knife, and we are thus enabled to apply the poison to successive portions of the nervous system, and thus demonstrate the immediate and direct action of the poison upon that portion of the cerebro-spinal nervous system which presides over respiration and the reflex actions.

Prussic acid, as we have satisfactorily demonstrated by numerous experiments, acts also upon the blood, and upon the muscular fibres and the sympathetic nervous system; but, as has been conclusively demonstrated by the experiments just recorded, the most marked phenomena, and those disturbances of the respiration which induce death, are due to the direct action of the poison upon the medulla oblongata.

English Beer a Cause of Gout.—According to M. Charcot, who has been lecturing on the subject at La Salpetrière, notwithstanding the drunken habits of the lower classes in Russia, Poland, Sweden, and Denmark, gout is almost unknown among them. In Ireland, and Scotland also, where whiskey is the national drink, gout is little known. Porter and sweet cider are accused vehemently; and Dr. Ball, a distinguished *agrégé* of the French hospitals, and a naturalized Englishman, analyzes carefully, for the benefit of French *savans*, our English beer; describing *porter* as highly colored, poor in alcohol, deprived of sugar, disposed to acid fermentation, and, owing to the torrefaction of the grain, containing a principle which is, perhaps, not foreign to its effects in the production of disease. This is the fatal cause of English gout, according to these gentlemen. Gout, however, prevails most in this country amongst the classes who never drink porter.

CLINICAL PAPERS ON EAR DISEASE.

By D. B. St. JOHN ROOSA, M.D.,

PROFESSOR IN THE UNIVERSITY MEDICAL COLLEGE.

NO. II.—FURUNCLES IN THE EXTERNAL AUDITORY CANAL.

Perhaps the simplest and best classification of inflammations of the external auditory canal, is that of Von Troltsch. He divides these inflammations into *circumscribed* and *diffuse*.

By circumscribed inflammation occurring in this part we mean simply furuncles in the passage. They generally arise in connection with the existence of furuncles in other parts of the body, and are, like them, very painful. They also produce deafness by mechanically closing the canal. Tinnitus aurium—noise in the ears—a symptom which is apt to be very troublesome in almost all other ear affections, is not generally present when furuncular inflammation exists. It may be, however, after the pus from the boil has been evacuated, and some of it perhaps remains in the canal and presses upon the membrana tympani and through it upon the *ossicula auditus* and auditory nerve. The reason that the tinnitus is absent in the early stages, is of course the fact, that there is no pressure exerted upon the drum by a circumscribed swelling of the canal.

There will be no difficulty in the diagnosis, if the ear be examined by means of the mirror or otoscope, and reflected daylight or sunlight. One or more circumscribed swellings are found in the caliber of the canal. Their usual situation is a point near the tragus, on the anterior wall, and we may have two or more at a time.

The proper treatment is to make an incision at as early a period as possible, and then to continuously apply warm water, giving the ear an uninterrupted warm bath, as it were. It makes no difference whether pus or blood be evacuated by the incision. The relief following is generally immediate in either case.

The incision is best made with a sharp-pointed curved bistoury, cutting from below upwards, and not with a scalpel down upon it, as the books usually advise. The incision can be made more quickly, and does not cause so much pain, as when made with the scalpel. The ear should be syringed with warm water after the hæmorrhage has ceased.

After the furuncle is opened, and the pain caused by it has disappeared, it is well to smear the passage with some ointment, in order to hasten the softening of the indurated tissue surrounding the furuncle, but as long as pain continues the use of warm water should be persisted in. Steam may also be allowed to pass into the ear from any sort of a vessel.

Leeches do not seem to do the same amount of good in furuncular inflammation as in the diffuse form.

The vapor of chloroform has been highly spoken of, allowing it to pass into the auditory canal, but I do not know much of it by experience, having been generally satisfied with the method of treatment above indicated.

We shall probably not be done with the case when one furuncle has been evacuated, and has healed; just as in other parts of the body, one boil is apt to follow another in rapid succession.

This brings us to consider the cause of this affection. I do not think I ever saw a furuncular inflammation of the external auditory canal in a patient who was in other respects in a physiological condition. It seems to be the evidence of a wrong state of the system of some kind.

Furuncles are very apt to occur in anæmic persons. I have seen several cases where they were troublesome after parturition, during which the system had been much exhausted, and perhaps the patient had not been under the most judicious management as regards the diet. When iron was administered, and nourishing diet substituted for slops, the boils ceased to recur. Last winter I saw cases in young ladies who were zealous attendants upon the *German*, and who spent large portions of the night in the ball-room, for quite long periods. They were not particularly anæmic, but they had no proper appetite, and were evidently suffering from the effects of an improper mode of life.

Regular hours, regular times for eating, exercise in the daytime, soon relieved these cases, but those who would persist in their dissipations did not recover until the season was over. In one case there were also hordeoli or styes, which are generally regarded as evidences of mal-nutrition.

It will be seen from this, that the local treatment is by far the lesser part of our labor in these cases of circumscribed inflammation of the auditory canal. We should be very careful to inquire as to the appetite, exercise, mode of life, and *specifically* correct anything which may be out of the way. It will not be enough to give general directions, such as "You must take exercise and live well," but the amount and kind of exercise should be indicated, the time of eating, variety of food, etc.; at the same time some one of the preparations of iron will generally be indicated.

The ear should be kept from the influence of cold air, when the patient is out of doors, by cotton, or an ear-lap; but the habit of thus protecting the ears in the open clear air, where there is no draught, should be abandoned when the ear is well.

VESICAL CALCULUS.

PASSAGE OF A STONE THREE-FOURTHS OF AN INCH IN CIRCUMFERENCE, THROUGH THE URETHRA OF A BOY TWO YEARS OLD.

By WM. MASON TURNER, M.D.

PHILADELPHIA.

The case which I beg leave here to report, occurred in my practice several years ago, in the city of Petersburg, Virginia. It was given very briefly in the *Virginia and Maryland Medical Journal*. As it is an interesting case, I am induced to lay it once again before the profession. On the 29th of August, 1860, I was sent for in haste, to see a child, suffering, as the messenger informed me, from retention of urine. The case had been seen by a brother physician, who sent word that I should bring a catheter. I found, for my patient, a handsome little boy (colored) just twenty-seven months old. The attending physician, baffled in his attempts to give relief, and, moreover, called away to another case, turned the little patient over to me. He was lying on his back, moaning most piteously, his countenance betraying acute suffering. The pulse was both frequent and quick, ranging in strokes from 120 to 135 per minute.

Before proceeding to explore the region of the bladder, I was led to examine the chest, by accidentally laying my hand over the right lung, and feeling a decided vibratory thrill. On auscultation I detected a pneumonia in the upper lobes of both lungs, and in the *second* stage; as bronchial respiration, bronchophony, and dulness on percussion were well marked. Upon inquiry I learned that the child had been sick a month previous, with measles, and having taken cold when recovering, had been complaining more or less since that time.

The bladder, to which I then turned my attention, was

enormously distended, protruding and hanging over the pubic arch, resembling in miniature somewhat the *pendulous belly* of pregnant women. The epidermis in the neighborhood of the bladder was red and shining, and I feared the formation of an artificial opening. The penis was much enlarged, and seemed to be infiltrated with urine. This was not the case, however, as subsequent examination proved. To add to the difficulties of the case, there was present a congenital phymosis, rendered ten times more rigid in its contraction by the swollen condition of the penis. It was a difficult task which I then set to work to perform, that of drawing away the urine of a boy, twenty-seven months old, under circumstances of such pain to the little fellow, and of such disadvantage to myself. The swollen and phymosed condition of the penis, and the great nervous irritability present in the patient, rendered it almost impossible to make even an attempt with the catheter. At the slightest touch the child would shriek and scream, until I actually thought the strained bladder would rupture before the violent muscular contractions would relax. Finally, after much patience and considerable manœuvering, my only assistant being an old lady, who managed to hold the child's hands, I succeeded in passing a small catheter through the hard, pursed-up ring of the phymosis, and as fortune decreed it, into the urethra. This *feat* I was compelled to perform several times, for the frantic efforts of the child dislodged the catheter and made my labor abortive. However, I placed my knees upon the lower extremities of the child, and in this position succeeded in passing the instrument once more into the urethra. Moving it slowly and cautiously onward, I soon had the satisfaction of reaching the bladder, which I knew by the sudden gush of the pent-up urine through the catheter. At the neck of the bladder I noticed a slight *gritty* feel as the catheter glided along; it was transient, however, and I thought nothing of it, attributing it to the ring of a cartilaginous stricture, which I have no doubt existed. The boy was immediately relieved, and fell asleep, while the urine, an enormous quantity, was flowing. That night I prescribed simply cold cloths to the penis. The next morning I called to see the boy, and found him much refreshed and improved by a good night's rest. The belly over the bladder had lost the prominent, *bullety* appearance of the previous evening, and had assumed somewhat more its natural proportions; yet it was still very tender. The penis still possessed its look of infiltration, and resembled a lump of translucent jelly. The boy had only once voided his water, and that in a very unsatisfactory manner, screaming at the top of his voice when the urine reached the urethral canal, and refusing most positively to make further effort. The result was, on my arrival, he was again unable to urinate. Once again my little catheter was brought into requisition with success. I thought, perhaps, the rigidity of the phymosis occasioned to a certain extent, at least, the difficulty in micturition, and I determined to operate for it at once. The operation was over in a few seconds, and I then saw that the retention was in no wise connected with the phymosis. Passing the catheter into the empty bladder, for the purpose of exploration, I detected the same *gritty* feel which I had remarked the previous evening. There was no mistaking the peculiar sensation, the touch was decisive; there was a foreign body occasioning all this trouble. In withdrawing the catheter, which I had used as a sound, I felt an opposing substance, and then with my thumb and forefinger detected an irregularly rounded tubercle in the urethra. After several introductions of the catheter, the tone was successfully hooked in the fenestra of the instrument, and was cautiously, slowly, drawn forward towards the *meatus externus*. Here I was beset by much difficulty. I dared not split the urethra, and yet it was extremely difficult to get a hold on the stone, which showed a constant tendency to retrocede. After much patience, however, and considerable manipulation, the *casus belli* was drawn near the external orifice, and neatly extracted with a thin pair of dressing forceps. The boy came near swooning, but soon revived.

A further examination, using the catheter as a sound, revealed, as I had already suspected, another calculus in the bladder. Lithogenesis was hereditary, it seemed, and yet the family record did not substantiate the opinion. The following are the dimensions of the stone: Length, five-eighths, and circumference, three-quarters of an inch; weight, forty-two grains; shape, semi-conoidal and semi-cylindrical, the presenting end corresponding to the apex of the cone. An analysis determined it to be oxalate of lime.

Owing to the irruption of the recent war, I was unable to follow up this case, but will simply mention that just before hostilities began I was again called to the little patient, and succeeded in getting away, by the same means as employed in the first case, another calculus, but much smaller than the first extracted. The noticeable feature in this case is, that a stone of such remarkable size *did* pass through the urethra of a *child two years of age*.

Original Lectures.

ADDRESS TO THE ALUMNI OF THE UNIVERSITY MEDICAL COLLEGE, N. Y.

By Prof. GEORGE T. ELLIOT, M.D.

Fellow Alumni of the University Medical College—The unexected honor of addressing you this evening, at the first formal meeting of the Alumni, has been awarded to me by the committee, representing the interests of 2,631 of our number, in such a manner that it could not be declined; and it has been accepted in the spirit which prompted the offer. As a native of this city; a graduate of the literary department of Columbia College; a doctor of medicine of this University; a lecturer for several years in the College of Physicians and Surgeons; and as one of the founders and professors in the Bellevue Hospital Medical College, I represent alike those affectionate reminiscences which have called us together this evening, as well as that solidarity of purpose, interest, and responsibility in which all these colleges are embraced.

The history of the past has shown that the prosperity of one enhances the prosperity of all, and the brightest hopes for the future success of medical teaching in this metropolis grow out of the harmony of feeling, the concert of action, and the honorable emulation by which they are distinguished.

The inevitable centralization of interests, which is begotten by the laws of trade and the natural advantages of New York, had foreshadowed the commercial preeminence of this city before its wondrous development has astonished the world. While the electric telegraph, pondered over by Prof. Morse in one of the rooms in this building, has so concentrated the facilities for business operations, as of necessity to develop the future of New York beyond all possible anticipation. Those long lines of telegraphic wire are the nerves of commercial life, the various cities of the country are the ganglia, but here is the busy brain of commerce which

coördinates and directs the vast ramifications of its monetary relations.

Such commercial supremacy dwarfs, of necessity, the relative status of literary and educational enterprises, while, in reality, favoring their development in every possible way. The great rewards of professional and literary life in this country are to be found in this city; and hence the ranks of ambitious men are steadily recruited from all the States by those who have the nerve and the capacity to enter the arena and compete for the highest prizes. The great hospitals of every country are found in its principal city.

There can, therefore, be no doubt of the eventual supremacy of New York as the great centre of medical education in this country, even if the astonishing progress of the last few years had not confirmed the anticipation. It is to the medical department of the University that the honor is due of first practically developing the claims of New York to be the chief medical school of this country; although the medical department of Columbia College and Rutgers College must for ever share the honor of laboring as pioneers in the field.

The experience in teaching, and the brilliant reputation of the founders of this college, turned the tide of students to this city, made its advantages known to the South and West, and attracted larger classes to their lectures than had ever been seen in New York.

In the twenty-seven years which have elapsed since its organization many changes have occurred in its Faculty, while some, full of years and honors, have passed away from among us, and rest from their labors. It is a fitting time to recall some of those personal reminiscences which are shared by so many of my audience, and it is to be hoped that the subsequent annual addresses to the Alumni of this college may gradually supply those data, interesting at the time to those who can confirm their accuracy, and furnishing the most valuable materials for the biographer and the historian.

When I first matriculated in this college in October, 1845, the lectures were delivered in the Stuyvesant Institute on Broadway, opposite Bond street, which belonged to the Faculty, and was subsequently sold by them after they had erected the splendid building, recently destroyed by fire, in East Fourteenth street, between Third avenue and Irving place. At this time the prosperity of the college was at its height, the spacious lecture-rooms were thronged with students from all parts of the country, but especially from the South and West. The Faculty, flushed with success, full of ardor, experienced, energetic, in the prime of manhood, and well-knit together, presented in the highest degree the cohesion, the discipline, the vigor, and the enthusiasm which represent the essential conditions for the prosperity of a college.

Of all the names which challenge my attention, it is right that the first place should be given to that of Valentine Mott, then Professor of Surgery, and more widely known in this country and to the world than any American physician has ever been before or since. To lecture on Surgery was for Mott a labor of love, never completely relinquished to the close of his long life. His image rises clearly before me as he alighted from the large old-fashioned gig in which he then preferred to drive; clad in spotless glossy black, without a crease or grain of dust, he passed with his pleasant smile and slightly bowed form through the throng of admiring students to his private room.

Although a fluent lecturer, Mott was rarely eloquent, and never sought to charm his audience by any grace of oratorical display. Students and physicians went to see and hear the self-reliant man who had devised so many bold and original surgical procedures, and was so renowned for the delicacy, the skill, and the success of his operations. In the gentle, placid, smiling face before them they beheld the surgical pioneer who had left so few of the great operations on the human body to be originated by others. As secure in his knowledge of relative anatomy as the mariner in the fidelity of his compass, Mott had passed boldly on from one triumph to another, had made the crooked ways straight, and illumined the path for all to follow. His devotion to the study of surgical anatomy was such, that to the close of his active life he rarely undertook an operation of difficulty without previous reference to the cadaver.

These minute precautions with which he guarded his operations against every avertable cause of failure, the intensity of his devotion to delicacy and success in his manipulations, were the foundation of his great renown, and distinguished every thought and act of his surgical career. To him each step of an operation always involved a solemn responsibility, though he might have discharged the same duty an incredible number of times before; and such was his enthusiasm, that the ligatures which he had applied to the great arteries were carefully preserved, and even shown to his successive classes. They were as hallowed to him as the trusty weapon which the successful soldier bears back from the well-contested field.

These qualities distinguished him as a lecturer, but detracted from his success. A feeling was left in the minds of many students that these operations might fall to their lot, but could only be properly performed by such a man as Mott, separated from them by impassable barriers. And thus the very vastness of his knowledge of the subject, and his extreme desire to impart all those details which had served him so well in such trying and unforeseen emergencies, somewhat obscured the student's perception of those few indispensable indications which alone he was fitted to comprehend.

"Ah," said the late Professor Gilman to me, "I wish that I had not been prevented by circumstances from delivering a course of lectures on a certain subject; they would have been better than any that I have ever given." And when I asked him why, he replied, "Because I would not have been embarrassed by any knowledge of the subject." But the very wealth of illustration and detail in Mott's lectures which embarrassed the young student, made them of priceless value to the practitioner, and to him who had grappled with similar difficulties.

How many living men there are who can endorse the statement made by the President of the College of Physicians and Surgeons at the formal meeting of the Academy, held after the death of Dr. Mott! "I never met Dr. Mott in any case," said Dr. Delafield, "without learning some fact of practical value."

According to an old Chinese proverb, "Tall towers are known by the shadows which they cast, and great men by their calumniators." Nor was Mott an exception to the law. But their voices are hushed in the presence of the grave; and while impotent during his long life to deprive him of his just meed of honor, they have for ever ceased their objections to his rank as the greatest surgeon that America has ever produced.

In 1850, Dr. Mott's health began to fail, and for a second time he restored its tone by a visit to Europe. His place was filled by Prof. S. D. Gross, now the successor of Mütter, in the Jefferson Medical College of Philadelphia.

Dr. Gross's resignation from the University led to the appointment of Dr. Alfred C. Post to the vacant chair.

The nephew of Dr. Wright Post, whom Dr. Mott venerated as the leading surgeon of his day, long a surgeon to the New York City Hospital, an untiring student, he now fills, with honor to himself and to the College, the chair which is identified with the lives of the leading surgeons of the country.

After his return from Europe, Dr. Mott accepted the proffered rank of Emeritus Professor of Surgery in the College of Physicians and Surgeons, but subsequently resigned that position to take the same rank and title in the University, which he held to the day of his death.

Granville Sharp Pattison was one of the founders of the College, and Professor of Anatomy when I was a student. The first idea of the establishment of this school was developed in his mind by a desire to settle in New York. He came from Philadelphia to lay his plans before Dr. John W. Draper, who, more than any other man, has shaped and directed the policy of this College from the hour when he consented to undertake its organization.

Pattison was no ordinary lecturer. His strongly marked individuality stood out in bold relief in whatever surroundings he might be placed by duty or inclination. His finely marked oval face, his commanding forehead, the quiet grace of his movements, the calm equipoise of manner which marked the man of the world, at home in the best bred circles, and fitted to shine in any society, all conspired to enhance that peculiar charm which the audience felt before a word had yet been uttered.

He needed all these and other qualities to supply the deficient voice and defective articulation which marred his elocution. It often happens, however, that the physical defects of a man of marked ability enlist the sympathy of his admirers, blunt the sharp edge of criticism, and form an additional bond of endearment. Without these drawbacks, Pattison would have been a great orator; in spite of them he succeeded in teaching anatomy so clearly, and in a manner so attractive to the student, that it will always be difficult to find his superior.

One secret of his success is to be sought in the striking contrast of his style to that of Mott. The professor of surgery and the professor of anatomy in a medical school, teach the same subjects in their different relations, and often meet on common ground. Perhaps Dr. Pattison was not unaware of the relief which it gave to the student when he taught the surgical anatomy of the neck, or of hernia, in simple graphic language, which penetrated like a sunbeam into the cloudiest intellect; or when stripping the subject of all the refinements and minutiæ with which it had been draped by the great surgeon, he pointed with that ardor, that demonstration of warm sympathetic feeling for the student of which he was supremely master, to the simple anatomical details, the clear cardinal facts, which alone they need remember, and on which alone they might rely.

It was formerly the custom to open the session by a week of introductory lectures—one evening being allotted to each chair—and I well remember the impression which Dr. Pattison made on one of these occasions. These addresses were prepared with care, read from the manuscript, and requested for publication by the class. When the time came for Dr. Pattison's address, the amphitheatre was lighted up instead of the lower lecture-room, and thronged with students. The doctor made his appearance in full evening dress, with blue dress coat and pumps. Using no notes, commencing in a low tone of voice, in his peculiar enunciation, struggling with his lisp, and the difficulty that he experienced in pronouncing the letter *r*, he proceeded to show that an exact knowledge of anatomy was indispensable to the trustworthy practitioner. The hushed silence with which his remarks were received showed the sympathy of the audience for the difficult articulation, and their confidence in the power of the man. But as he unfolded his argument, and dilated with his theme, his voice rose, the listless unimpassioned manner was lost in the eagerness and ardor of the earnest advocate; all the fiery energy of his nature, the reminiscences of years of heart-inspired teaching were fused in the glowing words which brightened the beaming faces of the class, until, at last, uncovering a superb dissection of the surgical anatomy of the neck, he pointed with fingers trembling with excitement to the relations of the vital parts to each other in illustration of his method of teaching, and concluding amid storms of applause, he left indelibly impressed on the mind of every student that it was hopeless to seek for a more trusty guide.

His was the skill—

> **"To breathe the enlivening spirit, and to fix**
> **The generous impulse in the glowing breast."**

After Dr. Pattison's death, his place was filled by Dr. William H. Van Buren, whose large surgical experience in army and civil hospitals, as well as his singularly clear and remarkably well illustrated demonstrations, lent the greatest interest to his lectures.

The identification of Professor Van Buren with the United States Sanitary Commission during the Civil War, has associated his name for ever with our national history; and the official history of the commission has recorded the following testimony of his colleagues to the value of his services.

"Dr. Van Buren was one of the members of the commission to whom it was indebted for services in the early period of its history, which, when viewed by the light of experience, it would seem impossible to have dispensed with. To his eminent professional reputation, which had done so much to secure a respectful hearing of the claims of the commission at the outset, he joined a calm and sober judgment, not only of what ought to be done, but of what, with proper effort, could be done. His former connection with the medical staff giving him a thorough knowledge of the defects of the system, gave also a practical value to his suggestions of the remedy which it was impossible to over-estimate. The commission did not hesitate to follow implicitly his counsel in all his suggestions of reform measures, and the wisdom and propriety of his advice have been fully confirmed by the experience of its whole history."

Dr. Darling, who had long since resigned his position as Demonstrator, and devoted himself with ardor to professional studies abroad, a Fellow, by examination, of the Royal College of Surgeons of London, has accepted the post made vacant by Prof. Van Buren's resignation, and stands a living link between the memories of the early college days and the active duties of the present.

The chair of Th ory and Practice has witnessed many changes, and has been filled by many of the ablest men in the country. The emphatic Revere, the scholarly Saml. H. Dickson, the classic Bartlett, the learned Meredith Clymer, who served with distinction as surgeon in the late war, the practical and clear-headed John A. Swett, who has left in his work on Practice the proof of his great ability, that graceful, apt, and finished clinical teacher, Dr. John T. Metcalfe, have successively discharged the responsibilities of a post now filled by Dr. Alfred L. Loomis, who has laid in the Bellevue and Charity Hospitals the foundations of his success.

The department of Materia Medica has always been identified with Dr. Martyn Paine, whose voluminous works attest the studious habits and the earnest convictions which have distinguished his long career. The days have gone when Dr. Payne used to canter to the college on his mettlesome black horse; but though bowed by the weight of years, and led by advancing age to withdraw from active duty in favor of Professor Thompson, neither his intellectual forces, nor his interest in the college, are in any way abated.

With the obstetrical chair, the name of Gunning S. Bedford has been associated from the beginning. The remarkable success which has attended the publication of his lectures, and of his college clinic, the rapid exhaustion of successive editions, the translation of his works into foreign languages, the approbation of reviewers and of students, attest the ability which marked his teachings. Retiring from the schools, he has thus left a perpetual legacy in the published results of all his studies. In his successor, Dr. Chas. A. Budd, the alumni recognize one to whom the interests of the chair are worthily confided, and who has added to its attractions by the assignment of Dr. Jacobi to the children's clinic.

Dr. John W. Draper, now Emeritus Professor of Chemistry and of Physiology, has been the executive officer and guiding spirit of the school. Earnest but calm as a lecturer, remarkable for the aptness and profusion of his illustrations, the concentrated manner, the simplicity of style, and distinctness of argument, never suggested a thought of that exceeding grace of language and brilliancy of metaphor which rendered Prof. Draper's introductory and valedictory addresses so remarkable, and which found a congenial theme in his eulogy on Pattison. The magnetic influence of Dr. Draper as a lecturer is felt in the sentiment of reserved force with which he penetrates an audience, in the possession of such qualities as are displayed in his wonderful work on the History of the Intellectual Developmen of Europe, and in his remarkable history of the Civil War in America. Each of these might justly claim the labor of a life; but his studies have been prosecuted while giving two distinct courses of lectures, writing an elaborate work on Physiology, a textbook on Chemistry, contributing original views to our knowledge of the laws of light and their relations to the development of plants; and, among other valuable discoveries, originating the application of the process of Daguerre to the taking of portraits from life.

He thus stands a pioneer in one of the most valuable inventions of the age, identified with the science and the literature of his time, an ornament to the University, and the pride of the Alumni.

Although no longer actively connected with the school as a teacher, he has the happiness of seeing the chairs of Chemistry and Physiology, made vacant by his resignation, ably filled by his two sons.

It is as though an elevated type of fissiparous germination had demonstrated alike the excellence of the stock and the vigor of the parent germ.

The University Medical College enjoys the honor of having inaugurated the era of clinical teaching in this city. The clinic of Dr. Mott has now expanded into those of Prof. Post, of Prof. Gouley, who brought to the Army of the Potomac the operative skill obtained in Bellevue, of Prof. Roosa cultivating his specialty with ardor; and while it awakened a short-sighted and mistaken opposition in the time of its founders, it was the first of those organizations which have since been developed in the colleges of the city. Although clinical instruction was previously given, to a certain extent, in the New York Hospital to those who had paid an extravagant price for a ticket of admission, neither the interest felt by the staff in the subject, nor the accommodations then existing in that hospital, or in the small theatre subsequently opened in Bellevue, sufficed for the necessities of the student.

The method of clinical instruction inaugurated in surgery by Prof. Mott, and in obstetrics by Prof. Bedford, bridged over the period of time which elapsed between the former comparative indifference to bedside teaching as an educational necessity, to the present, when our college clinics are beginning to yield in attraction to the superior advantages of our large hospitals, in which a spirit of honorable emulation has arisen already, productive of surprising results, and prophetic of incalculable benefit for the future.

And now, fellow Alumni, that I have embodied in this retrospect some of the reminiscences of the past, and some of the claims of Alma Mater to an exalted rank among the medical institutions of our country—let me ask how has it fared with you in the battle of life?

Many of our number are at rest. Some have fallen on the field of battle, or have succumbed to the pestilence. Many have revived their college associations and their friendships, after their arduous duties had been discharged to the wounded of both contending armies. Many have shrunk from the responsibilities and heart-aches which weigh upon the physician, and have sought in lighter duties a calmer and less heated life. Some have died in the very bud of promise, to whom the touching words of Newton are as applicable as they were to the young astronomer Cotes. "Ah!" said the unselfish Newton, "if Cotes had lived, we should have learned something." Others may be found in the very van of progress, cherishing the best interests of our profession, and a bright example to us all.

The vicissitudes of life have left their impress on us. Where are the light hearts, and the buoyant spirits which thrilled our pulses when we ascended this platform, and touched the long coveted diploma?

Eheu fugaces, Postume, Postume, labuntur anni! The resistless waves of time bear us onward on the tide of advancing years. We follow those who have gone before. Soon we shall feel that last regret that we had not done more and better in our day and generation, and then—

"Dust to dust, ashes to ashes."

Were we wise when we became physicians? Are those wise who recruit our ranks? I fear that many a heavy sigh proclaims the disappointed hope. The rosy atmosphere of youth has gone, the shadows deepen, the naked stony realities of life encompass our steps. We have our fits of gloom and disappointment. We are condemned to struggle against that immutable law of death, to which we must ourselves succumb.

Our consolation may be found in watching those engaged in other intellectual pursuits, if the gathered experience of our bedside lives has not already taught us the vanity and weariness of human endeavor. "For in much wisdom is much grief; and he that increaseth knowledge increaseth sorrow."

Where in the range of intellectual exertion can men find respite from care, or freedom from disappointment? Where is the field of study in which the physician cannot glean some scattered facts to stimulate his efforts and reward his labor?

Manhood has its ideal as well as youth. When the rude shock of the world has dispelled our first and brightest illusions, when the mirage has gone, the oasis vanished, and the illimitable desert stretches its long waste before us, then all the noblest qualities of our na-

ture which slumbered through the long peaceful years of ease, stir themselves within us and nerve us to the task. Courage and ambition sustain the drooping hope, patience supports the steps, and fancy paints the reward of enduring effort. Far above the trudging feet, the busy brain remembers, plans, devises, until again the arid scene is colored by the glow of manly resolution, striving for the same ideal, though stripped of the chimeras of youth. Disappointments no longer discourage, failures serve as fresh incentives, while true wisdom crowns the gathered treasures of the intellect with the insignia of humility.

In this spirit we recognize in all our trials the purifying discipline of life. To grow wiser is no longer all. To grow better is the thought which slowly blends itself with our purpose, and graces the rugged surface of resolve as the clinging ivy clasps the solid stone in its close embrace.

And so, turning more and more from the material to the spiritual, we find that the greatest love must come from the greatest knowledge, and thus the imperfect intellectual capabilities evolved from our being, though failing in so many efforts, take at last their highest and securest hold on faith in the omniscient Lord and Giver of life.

Survey the broad converging avenues which lead to intellectual distinction, and note how the physician can gather instruction and consolation from the lives of all who toil therein.

Mark the astronomer through the long and weary watches of the night, patiently augmenting the growing record of his observations. Compare him with the immensity of the worlds which he studies. A mere atom, a mathematical point with neither length, breadth, nor thickness, standing on the thin crust above the ever blazing fires which we call the solid earth, he has attuned his mind to the harmony of the spheres, and has extended his knowledge of the boundless limits of the universe by apparatus of wondrous mechanism, so that now machinery does his bidding, and records the results of his vigils with a precision and accuracy to which man himself could never attain. Privileged to read the laws which determine the majestic march of the heavenly bodies, the astronomer foretells the arrival within his sphere of vision of worlds unknown to him until their perturbing influences had heralded their approach. Interpreter of the oldest and proudest of the fair daughters of science, he reads the separate characters of nebulous masses, and recognizes in their immensity a stupendous aggregation of separate planets. The glory of all earthly pageants pales before the grandeur and solemnity of the scenes displayed by the aid of a few well constructed lenses. Copernicus, Galileo, Kepler, Newton, Herschel have passed within the veil. The fable of Prometheus has been realized, and the heavenly light streams through countless telescopes from regions dark to the unaided eye, and illumines the soul.

But consider that among all the countless numbers of gifted men who have labored in this the most ancient domain of science, how very few there are who have advanced its limits. Consider their anxieties, their disappointments, and even their persecutions, and you will see that no achromatic lenses can be contrived to shut out the gloom of discontent—"For man is born to trouble as the sparks fly upward."

The microscope of the physician, planned in obedience to the same laws of light which govern the construction of the telescope, discloses unimagined marvels worthy of comparison with the revelations of the astronomer. He finds in the infinitely small, as the astronomer finds in the infinitely great, wondrous types of beauty, and infinite illustrations of that obedience to law, so grandly illustrated in the movements of the heavenly bodies. The hairs of the head have been numbered, but such labor bears no relation to that which has gradually resolved the tissues of the body into their ultimate elements, and traced them through their predestinal transformations; which has found such startling evidences of design in the ultimate capillary vessels of different organs; which has disclosed those serried ranks of ciliated epithelium, with their sleepless vibrations, lining certain recesses of the body; which has classified the infusoria, recognized them in impalpable grains of microscopic dust, and shown in their migration and development another evidence of that grand subordination to law, set like the seal of the Creator on all his works; which has detected in the excrementitious parts of man and birds those sparkling crystals shedding a flood of light on the treatment of disease, and those shells of transcendent beauty, baffling the engraver's art; which has unravelled the coverings of the ovule, defined the laws of its growth, and disclosed in the segmentation of the vitellus the first of those wondrous changes in the progressive and uniform development of fœtal life.

And, as the astronomer finds that the elaborate investigations of ages only serve as starting-points for new discoveries which astound his intellect, and make him feel with Newton that he has merely gathered pebbles on the sea-shore of knowledge; as he recognizes in the "sweet influences of the Pleiades" the forces which overthrow his heliocentric theories, and direct again his hopeless labors in search of the unattainable; so does the microscopist recognize in the teeming myriads of unseen life, within, beneath, and around us—in the mechanism of their organization, so minute that years of patient study are demanded for a few of its component parts, so perfect that the inventive mind of man hails with gladness in these models unsurpassable illustrations of the adaptation of means to ends—evidences of the inexhaustibility of his researches, and of that power which holds the earth in the hollow of his hand, and has known all things from the beginning.

What creations of man are more enduring, and more distinctive of his preëminence, than the varied types of architecture? From generation to generation, they symbolize the religious aspirations of peoples and the ambitious hopes of kings. Lost languages are graven on their walls, and buried for centuries in oblivion, until, after the lapse of ages, the Rosetta stone is found and the dead past speaks to the living present. For thousands of years they bid defiance to natural laws of decay. Empires crumble, nations become extinct, seas and rivers change their barriers, the name and memory of architect and builder are gone for ever—but still the solid structure stands.

But the physician recognizes in the long bones of the human skeleton that union of strength with lightness which has done so much for architecture, and sees in the mechanism of the pelvis that combination of the principle of the arch and the suspension bridge with which the greatest triumphs of engineering have been achieved. Pursuing his researches through the realms of nature, he finds in the nests and homes of animals a perfection of adaptability and contrivance which challenge our lasting admiration while they humiliate our pride.

How touching are those discoveries of facts illustrative of domestic life which the enduring pyramids transmit more surely than the proud memory of their founders! In a leisure moment the humble laborer toiling with a hundred thousand of his fellows on the slowly rising structure, scratches on the sides of a stone the name of the reigning Pharaoh. The pyramid is finish-

ed. Pharaoh and people sleep with their fathers. The name of the king has lapsed from the memory of tradition, but the careless record of the poor workman transmits through thousands of years that name of his supreme master which the stately pyramid had failed to guard.

From the legended tomb the mummy is at last borne to countries of which the existence was not even surmised in its lifetime. Strange forms and faces watch with mingled curiosity and interest the unwrapping of the successive covers, but when there falls from the shrivelled armpit the flower which has been pressed there through centuries, the unmistakable token of a last affectionate thought rolls back the buried ages, and the electric spark of sympathy flashes from the unseen past into the living heart.

Customs and languages may disappear, the form of men may change with the influence of climate and mode of life—but the same tear falls from the mourning eye today which bedewed the mummy of the Pharaoh—through all recorded time the human heart thrills to the same human emotions.

They slumber in all their vitality through centuries of time, but at the fitting moment their talismanic influence is felt. The buried grain of wheat from the Egyptian tomb ripens at last into the golden harvest of another hemisphere; the symbols of joy and sorrow engraven on stones long hidden in Egyptian and Assyrian sands, touch the same chords of feeling now, and proclaim the brotherhood of man.

How wonderful are the contributions of the literature of the past to the physician of to-day! The dead and buried languages yield to him their hoarded treasures of wisdom. He sees in the experience of ages the expanded experience of a life. With all the stupendous achievements of science he finds in the aphorisms of the fathers of medicine the barriers which limit his progress to-day. "Vita brevis, ars longa, occasio præceps, experimentum periculosum, judicium difficile." Generations of scientific men have left the proud record of their discoveries as starting-points for the enthusiasm and the genius of their followers, but, as the boundaries extend, new and more fruitful fields for observation widen the horizon. "Plus on s'élève, plus l'horizon s'étend." The strivings of science for unattainable knowledge illustrate the startling mathematical law that a thing may be infinitely greater than a thing infinitely great.

Philologists have at last unlocked for us the sacred books of the Hindoos, and the physician finds in the Sanscrit of thousands of years ago, in the record of those laws which govern the development of the offspring of mixed races, the same results which our experience in the South has taught. Let us hope that the prophetic words of the wise old Hindoos may not apply to us. "Every country," they say, "in which the purity of type is defaced by admixture of races is soon destroyed with its inhabitants."

The artist steeps his senses in types of beauty, and harmonizing all their attributes in the rich tints of his poetic fancy, the result is shown in "the statue which enchants the world," or in the mellowed splendor of the canvas before which generations bow in hopeless emulation.

The physician deals with life itself. The wasted form, the pallid haggard face, the sunken suffering eye lie before him on their couch of pain. The feeble cry of infancy, and the stifled anguish of maturer years echo within his heart. See in the results of his labor the wondrous change. The parched lips are wreathed with smiles, the sparkling eye, the rounded outlines, the rich blood which mantles in the cheek and warms the swelling heart, the merry peals of laughter surely demonstrate the advancing power of his art. The writhing limbs, contorted with pain, relax themselves, and bathed in refreshing sleep acknowledge in graceful attitudes the magic power of an anæsthetic. The gibbering soulless face of the insane is lighted up again by the dawn of returning reason, and transformation more wonderful than that of the fabled Memnon, bursts forth in songs of praise.

And thus, amid all the cares of life, the true physician finds his consolation in the contemplation of his ideal, and in his warm intellectual sympathy with all students of nature's laws. No mere routinist, deserving the sarcasm of Voltaire, and pouring drugs of which he knows little into a body of which he knows less; but, humbly recognizing the limitations of all knowledge, he shares this humiliation with all earnest seekers after truth, and points serenely to the past in evidence of the progress of the present.

Progress of Medical Science.

PROCESS FOR PRODUCING HYDROGEN.—M. Heurtebise describes in a late number of *L'Invention* an economical method of obtaining hydrogen gas. He places charcoal in a retort and raises it to a red heat; then passes over it a stream of carbonic acid, thus forming carbonic oxide. Into another red hot retort he passes a current of steam and the gaseous contents of the first retort, and the products in the second retort, resulting from the decomposition of steam, are carbonic acid and hydrogen gases, which are separated, and the carbonic acid is again used in the first retort. The interesting process, described as new in the French journal, has been long used in America, particularly by those experimenters who have aimed at mixing more hydrogen with the large class of hydrocarbons which are very rich in carbon, and therefore liable, from imperfect combustion, to give off fine particles of unconsumed carbon in the form of smoke.

TANSY IN EPISTAXIS.—Dr. C. P. Uhle (*Medical and Surgical Reporter*) has tested quite thoroughly the virtues of the *tanacetum vulgare* as a remedy in epistaxis. An accidental application of a tansy leaf to the part while a student, completely controlled the hæmorrhage in his own person, and has never since failed in his hands. In some instances the simple aroma of the plant proved sufficient.

THE BICHLORIDE OF METHYLENE, the discovery of which is attributed to Dr. Richardson, of London, is claimed to differ from chloroform in the rapidity with which it produces anæsthesia, in the prolonged insensibility which results from its inhalation, and in the facility with which complete anæsthesia may be reëstablished by the reception of a very small quantity of the vapor when the effect begins to diminish. There is said to be no secondary excitement in the action of this agent, no convulsive movements and no vomiting. The patients upon whom experiments were made with the bichloride of methylene glided softly into complete unconsciousness, and after continuing under its influence for periods varying from half to three-quarters of an hour, with very slight variation of pulse or breathing, recovered their consciousness as quietly as they had lost it.

NATURE AND MODE OF PROPAGATION OF PHTHISIS.—Dr. William Budd (*Lancet*) expresses a conviction that phthisis is a true zymotic disease, of specific nature, never originating spontaneously, and perpetuated solely by the law of continuous succession, and that the tuberculous matter itself is or includes the specific morbific

matter of the disease, and constitutes the material by which phthisis is propagated from one person to another.

Experiments with Bromide of Potassium.—Messrs. Eulenburg and Gutmann have stated, before the Academy of Medicine of Paris, that doses of from thirty to sixty grains, either by the stomach or injected under the skin, kill a rabbit in from ten to forty minutes. Smaller doses momentarily disturb the action of the heart, and paralyze the power of moving and feeling, causing a few antecedent shivers. On a post-mortem examination of the animals, no change, but some congestion of internal organs is found. With frogs, a subcutaneous injection of one grain to two causes, after ten or fifteen minutes, loss of movement, reflex action and feeling, with arrest of respiration, weakening and infrequency of cardiac ventricular action, retardation of peripheral circulation, and lastly, complete diastolic arrest of the heart's action. These effects are attributed by Messrs. Eulenburg and Gutmann, not to the bromine, but to the potassium.—*Lancet.*

Subcutaneous Incision in Carbuncle.—"I have had several opportunities of seeing, at the Hôpital St. Louis, in the service of M. Guérin, cases of anthrax, more or less grave, treated by his method of subcutaneous incision. This proceeding counts many partisans among us. It consists in plunging in the centre of the anthrax a straight bistoury, which is immediately insinuated on the flat under the skin beyond the limits of the swollen part; and, as soon as the limit is passed, the cutting edge of the instrument is turned towards the deeper parts, to incise them from the circumference to the centre, till the sensation felt indicates that resistance is overcome. This first incision only indicating one radius of the diseased surface, three others are made which converge towards it to the point at which the bistoury was introduced. When the integuments offer a mortified point, or an orifice, it can be used for introducing the instrument, without its being necessary to divide the skin to however slight an extent. The success of this operation, says Dr. Guérin, seems to solve the question of the seat of anthrax; for, if it be practised at the outset of the malady, it arrests the march of it, and opposes the mortification of the skin. Often the cellular tissue suppurates, and is eliminated under the form of a 'core;' while the skin presents no alteration. The subcutaneous incision of anthrax has the special advantage of relieving the patients from the liability to erysipelas and to purulent infection. Besides, this means is not very painful; for it spares the skin, which is of all the tissues that of which the incision produces the most pain. Finally, it does not give rise to a deformed cicatrix—a consideration which is not to be disdained when the anthrax is seated on the face or any other uncovered part of the body. After the incision, emollient poultices are applied; and in all cases the cure occurs more quickly than by any other treatment." *Paris Cor. British Med. Journal.*

Diagnosis of Polypus Nasi.—Obstruction to the nasal passages, due to a thickened condition of the mucous membrane lining the cavity, is without doubt one of the commonest sources of error in the diagnosis of nasal polypus; for the lower turbinated bone, covered with its thickened mucous membrane, is a prominent object in the nostril of a patient suffering from this disease, and an obstruction to the passage is at the same time a marked complication of its presence. The practitioner is thus too often misled into the idea that a nasal polypus is the cause of all the symptoms. The external appearances, however, of the parts involved in these two conditions are so different that such an error of diagnosis should not be made; for the nasal polypus has usually a transparent, pale, succulent aspect, whilst the mucous membrane covering the turbinated bone is of a dull, congested, and more solid nature. It is also to be observed, on examination, that the mucous membrane covering the turbinated bone is continuous with the same membrane covering the nostril. This latter fact is readily seen, and, in doubtful cases, is sufficient to make the diagnosis clear.—Thomas Bryant, F.R.C.S., *Lancet.*

Does the Liver form Sugar?—The *glycogenic* function of the liver, as it has been termed, which was regarded a few years ago as a well established point in physiology, has been called in question, lately, by means of sundry experiments going to show that it is not produced in that organ until after death, and that its production is due to a kind of fermentation which can only take place in stagnant blood. Such, at least, is the claim made by Prof. Schiff, of Pisa, as stated in a letter from that city, written by a correspondent of the *Richmond Med. Jour.* The Professor found that a ligature drawn tightly for forty minutes around the thigh of a rabbit produced a flow of sugary urine lasting twelve hours, and that pressure with the finger upon the abdominal blood-vessels of a rabbit for five or eight minutes produced the same effect, which lasted upwards of two hours. His theory of diabetes is that the sugar results from a ferment in the blood which has not the power to act in the normal condition of the body, but which is enabled to operate when the circulation in the liver and other parts is interfered with by paralysis of the vaso-motor nerves which supply the blood-vessels. The therapeutic indication derived from this theory is to prevent or annul the evolution of the ferment in the blood of a diabetic patient. This, it is suggested, might be attempted by the sulphites and hyposulphites of Polli and others. Diabetes, according to this view, becomes a *zymotic* disease. Whether we have gained much in the treatment of it, through the indefatigable labors of modern physiologists, is a question. We may, at least, felicitate ourselves that, sooner or later, these labors will be brought to a useful bearing on practice. By such thorough and laborious researches as distinguish the age in which we live, truth must be developed. Though the harvest be long delayed, yet it must come in the course of events. As the matter now stands, we are not aware that the treatment claimed to be "rational" can demonstrate its superiority in practice to that which is purely empirical.—*Pacific Med. and Surg. Jour.*

Danger attending Eye-washes containing Preparations of Lead.—From practical observations made at the Hospital of St. Sauveur at Lille, upon the evil effects of collyria containing acetate of lead, quite frequently employed as an astringent in light cases of ophthalmia, a precipitate of lead was observed upon the cornea, a layer of chloride of lead, which renders it dim, and forms erosions upon it by destroying its epithelium. Vessels are developed upon the cornea, as it were, to resist this morbid process, and the precipitate, after its disappearance, leaves behind it an ulceration of the cornea and pannus, which it is very often very difficult to remove—in fact, a greater evil than that it was first intended to remedy. The sight of the right eye was thus completely lost in a case for whom the following collyrium had been prescribed: Subacet. lead, ʒ ss.; Sydenham's laudanum, gtt. xx.; dist. water, ℥ v. M. This is barely useful in some cases of pannus; and even blennorrhagic inoculation, instituted in Belgium, seems preferable in these cases; in proof of which several cases have been published in this "Revue." It is thus safer to erase it entirely from the list of eye-washes.—*Canada Med Journal.*

Separation of Epiphyses of lower end of Humerus.—Mr. Robert W. Smith, F.R.C.S.I., in an address upon Surgery delivered before the British Medical Association at its late meeting in Ireland, thus remarks upon the diagnosis of this form of separation:

"The symptoms which belong to it, in common with fracture above the condyles, are the following: Shortening, crepitus, the removal of the deformity by extension, and its tendency to recur when the extending force is relaxed; the presence of an osseous tumor in front of the joint; the increase in the antero-posterior diameter of the elbow. It differs from the supracondyloid fracture in the greater transverse breadth and regular convex outline of the anterior tumor; in the existence of two tumors posteriorly; in the loss of the normal relation of the olecranon to the condyles. It resembles dislocation of both bones of the forearm backwards in the following particulars: The transverse diameter of the anterior tumor is the same in each case; so also is the antero-posterior breadth of the elbow; in both the olecranon ascends above the condyles, the limb is shortened, and two osseous prominences can be distinguished posteriorly. It differs, however, from luxation in the existence of crepitus, in the tendency of the deformity to recur, and in the circumstances of the anterior tumor being destitute of trochlea and capitulum, and the two posterior tumors being nearly on the same level."

Ephidrosis Cruenta.—Dr. McCall Anderson, at the meeting of the British Medical Association, related a case of the so-called bloody sweat. The patient was a lady fifteen years of age, who, in connection with defective and irregular menstruation (she commenced menstruating at the age of eight) suffered from attacks of hæmorrhage from the skin from oval or round erythematous patches situated symmetrically on the face, arms, chest, and legs. The outbreaks occurred very suddenly, generally without premonition. The patient would know however at once of an attack by a peculiar sensation, and when the part would be immediately exposed the cuticle appeared to have melted away, and a "complete dew of blood," was detected. With the exception of the menstrual derangement and the cutaneous phenomena, this young lady appeared to be in perfect health. The general tonic course was pursued, with stimulating hip baths at the menstrual epochs, and afterwards with Fowler's solution. She eventually entirely recovered.

Considerations Suggested by the Study of One Hundred Cases of Stone in the Bladder of the Adult Recently Operated on. By Sir Henry Thompson.—The cases were not selected, but were simply those which had occurred in the author's practice during the last three years and a half. Not a single case applying was refused operation; that, in the worst cases, being the only chance of life. They were all adults, the children's cases being omitted. The following facts were noted. Of the 100 cases, 84, or about four-fifths of the total number, were operated on by lithotrity and 16 by lithotomy. The mean age of the 84 lithotrity cases was 62½ years; among them were no less than 21 cases of 70 years and upwards, 2 being upwards of 80 years of age. Among these 84 cases there were only 4 fatal cases. The lithotomy cases, 16 in number, had a mean age of 63½ years. The youngest was 42, the oldest was 80 years; 6 were above 70 years of age, including 1 each of 77, 78, and 80 years; 6 cases were fatal. Of the entire 100 cases of operation upon unselected patients, having a mean age of 62¾ years, and submitted to either lithotrity or lithotomy, there were 90 recoveries and 10 deaths. These cases must be considered as less promising cases than the product of any given district. Four propositions were deduced from the facts stated. 1. Lithotrity is the most successful operation for at least four-fifths of all cases of stone in the adult which come under the surgeon's notice at the present time, a statement which is more definitely expressed in the fact that the rate of mortality for such cases in this series is barely five per cent. 2. Lithotrity can be thus successful only when it is performed on a definite system in accordance with certain practical rules which experience has determined, and which can be laid down. 3. Cases of calculus, in which one of the two operations, lithotrity or lithotomy, ought not to be performed, are excessively rare. 4. By exercising an ordinary degree of vigilance for adult patients suffering from symptoms of urinary disorder, every case of calculus may be discovered in an early stage, may be successfully treated by lithotrity, and, consequently, the operation of cutting for stone may be rendered obsolete, or applicable only for some very exceptional example which has been developed as the result of extreme neglect or ignorance.—*British Medical Journal.*

Acute Rheumatism by Syrupus Calcis.—Dr. C. E. Buckingham (*Boston Medical and Surgical Journal*) speaks highly of the beneficial effects attending the administration of this medicine in acute rheumatism. He has used it in doses as large as forty-five drops every two hours, but generally thirty drops have been sufficient. He cautions against its use in the form of a pill, or dissolved in water, and prefers milk as the vehicle. He has never found alkaline urine to result from its use, no matter how large or frequent the dose. He prefers to have it made of caustic lime. "The best formula," says he, "would be to mix two ounces of lime unslaked and eight ounces of sugar together in the mortar, and pour over the mixture a wine pint of boiling water. Add boiling water enough to make up the pint, and filter. By the use of boiling water, the operation is more rapid and the formation of lumps is avoided."

Splanchnoscopy.—If one holds an egg before a bright light, it is seen to be translucent. If a bright light were introduced into the stomach, we could obtain a tolerably fair view of its anterior and lateral parieties, by a similar property of translucency. Impossible as this demonstration would seem to be, it has been successfully performed by M. Milliot, of Paris. He introduces into the stomach glass tubes of small calibre, containing two platinum wires, connected with the electrodes of a powerful battery—the apparatus of Middedorpf he prefers—and thus kindles an intense light in the cavity. Tumors in the abdominal walls can thus be demonstrated, indurations and ulcerations detected, and, indeed, to what extent diagnosis may not be facilitated, it were premature to say. Certainly the idea is novel and worth considering.

The Influence of Stricture of the Pulmonary Artery on the Formation of Tubercle.—M. Lebert, the eminent Professor of Breslau, in a paper sent to the Academy of Medicine of Paris, comes to the conclusion that the stricture above named, at the origin of the vessel, has a tendency to produce an extensive and progressive tuberculosis, the characters of which may be clinically and pathologically ascertained.

Nævi by Nitric Acid.—Mr. Thomas Smith, F.R.C.S., in some clinical papers on the surgery of childhood, recommends the application of nitric acid to nævi in preference to any other caustic, or to the knife.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

GEORGE F. SHRADY, M.D., EDITOR.

THE PROPOSED CHANGES IN OUR COLLEGE SYSTEM.

A CIRCULAR has recently been addressed to the various Colleges, asking for a concerted action on their part upon the several propositions offered by the late Teachers' Convention in Cincinnati. The committee that represents this association, having a more or less permanent character, are perfectly competent to present the matter officially before the different Medical Schools, and in that light this last appeal for reform should undoubtedly be viewed.

They take for their basis of action the resolutions passed not only by the Convention but by the American Medical Association; and as our readers are already familiar with that document in detail, it is unnecessary here to do more than give an outline of the scheme. In brief, then, the changes proposed may be summed up under four heads: First, a positive standard of preliminary education; secondly, a longer time in which to acquire a knowledge of the various branches of Medical Science and Practice; thirdly, a systematic and successive order of studies for the student; and lastly, a certain amount of direct clinical instruction in a public hospital, as part of the senior course.

We have from time to time taken occasion, in our discussion of various matters connected with Medical Education, to urge the adoption of the suggestions therein contained, severally and collectively, and to endorse *in toto* the action of that body. We have not only been of this opinion, but have been ready to go a step or two farther in upholding measures that, under the present system, would seem almost impracticable. But this is by the way.

The objects of the circular which is before us are not only intended to explain away many of the arguments which have seemingly been brought forward by some of the schools against the resolutions referred to, but also to fix a period to the present system of medical instruction. Its first intention has been, to our way of thinking, well carried out, and we have only to hope that its second object will be also attained in an equally satisfactory manner.

In reference to the question of preliminary education we have fully expressed our views, and the plan which we took occasion to suggest was the examination of the students by some competent persons other than the faculty, in order that no plea that any unfairness or partiality could be brought forward. This at the time we believed was practicable, and we are still of the same opinion. There may be some other means adopted to insure this end, but this matters not, so long as the spirit of the resolution is carried out. The committee have, with some show of policy, merely presented the necessity for the adoption of some feasible means without suggesting anything definite. This is hardly the wisest course that could be pursued, inasmuch as it is advisable to form as a responsible body a distinct platform upon which all points at issue must be directly settled. A failure to distinctly define the manner in which these preliminary examinations should be carried on may still leave the whole question open, a prey to misconceptions and to the temptation of practically ignoring the subject altogether.

On the other proposed changes the committee is more to the point. In regard to the increase in the members of each college faculty good reasons are given. The contemplation is to give four lectures per day to each class throughout the whole college term of six months. We cannot see how this can be objected to by any faculty. The necessary increase of their members will so divide the labor as that each one can perform his duty to himself and to the students. To the supposed decrease in the income of each professor by the adoption of this course the committee have offered a satisfactory and conclusive answer. The increase in the faculty they assert is amply compensated for pecuniarily by the requirement that each student shall pay full fees for three courses of lectures instead of two. With this the teachers can find no fault, and the student will not be liable to demur, especially when no choice is left him in order that he may be sure of his diploma in the end. The increased expense for the whole term will not be felt any more for the third year than for the two previous ones, while in the end the increased outlay on his part brings him a richer premium in the allowance of extra time to benefit by the instruction which he receives.

The section referring to the branches to be taught during each term was simply for the purpose of naming a definite course to be pursued by each college, so that such a uniformity in the general system might be obtained as would allow students of different classes to transfer themselves to different colleges without occasioning confusion.

In order to obviate embarrassment in making the change from the present system of college instruction to the one proposed, the committee prudently suggest "that all students who have so nearly completed their period of study at the time fixed for making the change that an attendance on an additional course would ren-

der them eligible to graduation, should be allowed to complete their course by attending the Senior department under the new arrangement; while all who are in the first half of their period of study should be subject to the new arrangement in full." This proposition is an eminently proper and practical one, and should effectually do away with the principal obstacle to the speedy carrying out of the new plan.

The time set for the inauguration of these changes is during the winter term of 1868–9, and it strikes us that there is ample opportunity offered to all the colleges to discuss the matter by answers to the following questions by the committee:

1st. Do your faculty, together with the governing authority of your College, approve of the several propositions as a whole?

2d. If you do not approve of the plan of revision as a whole, what changes would you suggest?

3d. If you approve of the plan as a whole, or of all its essential features, will your College be ready to adopt it practically, and issue your Annual Announcement for the College term of 1868–9, in accordance therewith; provided all the principal Medical Colleges in this country (or at least those in the cities of Boston, New York, Philadelphia, Baltimore, Richmond, Charleston, New Orleans, Louisville, Cincinnati, St. Louis, Chicago, Buffalo, and Albany) will agree to do the same at the same time?

These answers are to be addressed to the Chairman, Dr. N. S. Davis, of Chicago. We hope that every respectable Medical College in the land will consider it a bounden duty to give the subjects referred to the fullest consideration, and be prepared when the time comes to agree, if not entirely upon the plan as set forth, at least sufficiently so to insure that uniformity of action which shall crowd out every element but honorable competition and an earnest desire to raise the standard of Medical Education.

There is no reason why a response should not be received from every College by the committee before the first of March next, when opportunities would be given to call another Convention of Medical Teachers, and have a report presented to them in due form.

What general practitioner returning from an obstetric call, after having spent with his patient many weary hours, has not felt that it would have been an incalculable relief to him to have shifted the case upon some other one? There is no department in medicine where so much time is spent which is so little recompensed as in obstetrics; and, in view of that fact, the physician has often rightly wished for some substitute who might be competent to care for all his ordinary cases.

The persons to whom we naturally look for a performance of this part of the practitioner's duties are properly educated midwives. It is well known that the plan of confiding obstetric cases, when of simple character, entirely to such females has been for a long time, and still is, in successful operation in Europe; in fact, many of our German and French brethren who are practising in this country are in the habit of entrusting all their cases to them with the most satisfactory results. The midwives referred to are in general exceedingly trustworthy, and being educated to send for the physician whenever any other part than the head of the child presents, they are not likely, unless designedly, through presumption of knowledge, to blunder by incompetent interference.

We are confident that such a system might be inaugurated in this country, and we are equally sure that if it were, the profession generally would give it their hearty support. A good plan would be to form a corporation in connection with some hospital, which should be legally qualified to give the suitable instruction to well recommended applicants, as the necessities of the case require, and also to issue licenses which would be held in the light of diplomas for practice in this particular department and at a particular time; beyond that it is not necessary that we should go. If a well organized corps of obstetric lecturers were established, and regular lectures upon the duties of attendants upon natural labor delivered, it would be calculated to turn the tide of female medical education into a more natural, useful, legitimate, and profitable channel.

We are pleased to learn that the friends of Dr. W. Marsden of Quebec, the well known sanitarian, contemplate presenting him with a handsome testimonial in order to show their appreciation of his energy and ability in connection with the establishment and improvement of quarantine regulations. Such a mark of favor, which could not be more worthily bestowed, points with significance to the probability of the appointment of the distinguished gentleman as chief of the Sanitary Bureau of the Federal Kingdom.

In obedience to an implied promise to further discuss the matter of recipes duplicated without proper authority, we now deem it expedient to recur to the subject.

We have already expressed our views upon the moral aspects of the question—and here we use the adjective in its broadest sense—and, at the same time, without any attempt to forestall the judgment of the profession, we more than intimated that the prescription belonged to the physician *in fee simple*. Since then, through the kindness of Dr. O'Sullivan, who has been prominently identified with the movement, we are enabled to lay before our readers what is technically known as a "legal opinion."

First.—The prescription is a direction from the physician to some druggist to put up for and prepare for a patient's use, a certain medicine. When the druggist performs this act and files away the prescription, he has no right to again put up or prepare medicine from that prescription, unless he does so by the order of the

physician who originally gave it. He has no more right to do so than a merchant would have to deliver on a written order for one barrel of flour sundry barrels, after the one called for was delivered.

A more important feature is, however, involved in the matter of physicians' prescriptions being duplicated by a druggist, without the physician's authority or instruction, which is that the medicine so duplicated may be entirely unsuited to the patient's changed condition of health, which the druggist has no opportunity of knowing. No one is capable of judging in such matter but the attending physician. The druggist that duplicates a physician's prescriptions, without the physician's orders, commits a crime against society, inasmuch as he permits medicine to leave his store which may cause the death of the person to whom it is administered.

Second.—Medical societies have a right to prescribe and establish a rule for the government of druggists in such matters, which no doubt druggists would carefully observe. This would save the medical profession from many charges of mal-practice, and many persons from the injuries resulting from the continued use of a medicine not advised or prescribed by a physician.

Reviews and Notices of Books.

CLINICAL LECTURES ON THE PRINCIPLES AND PRACTICE OF MEDICINE. By John Hughes Bennett, M.D., F.R.S.E., Professor of the Institutes of Medicine, and Senior Professor of Clinical Medicine in the University of Edinburgh, etc., etc. Fifth American from the Fourth London Edition. With five hundred and thirty-seven illustrations on wood. New York: William Wood & Co., 61 Walker street. pp. 1022.

WE remember what a treat we enjoyed as a student when we took up Watson's Practice of Physic, and read it through in course. It was an oasis in the desert of slipshod and dry medical literature, which invigorated the young traveller along the pathway of medical knowledge for many a waste beyond. Here is another book which must give to the student the same relief that did the classic work of Sir Thomas Watson. It has been adjudged superfluous to speak for books that pass through such numerous editions as the one before us—they speak for themselves. Yet, when an author so eminent as John Hughes Bennett takes the pains which have been here taken to keep his works abreast with the most advanced state of medical knowledge, it demands more than a passing recognition. The sections have nearly all been retouched, and the peculiar, and, we believe, very generally accepted views of the author have received new explanation and verification. Dr. Bennett's mode of conducting a clinical course must certainly commend itself, as it has already to the students of the former editions, to those who study the present one. The only wonder is that in the United States, where we have such advantages for clinical instruction, we do not make better use of them. Too many of our colleges are pleased when the physician or surgeon in charge makes a great impression on the wondering student, but fails to give him any instruction. This is the fault of our system, and not of our teachers.

Students in our hospitals should hear and see more for themselves, and be questioned by the clinical lecturers. Any one who has seen the method of clinical instruction as it obtains in the wards of Oppolzer and Skoda, in Vienna, must draw painful comparisons when he visits those of our eminent teachers; but, let it be remembered, the comparison is not between the teachers, but the methods, for our instructors are certainly as able and interesting as those abroad. Private instruction in New York is doing the work that ought to be done in the clinical wards before the whole class or sections of it.

In the part of the work on the examination of the patient, the physician will find an account of the use of the laryngoscope, illustrated by wood engravings, which make every special book on this subject merely a luxury; and so with the microscope. Velpeau's note in the second section, showing by statistics that morbid growths may be removed and allow the patient immunity for years, is valuable as giving a fixed standing-point where so much is mere quicksands of conjecture. Dr. Bennett concludes from the facts he presents, "that the possibility of permanently eradicating cancer may now be considered to have been incontestably demonstrated."

The theory of change of type receives new attacks from our author, and his views are sustained with interest and vigor. He regards it as "altogether fallacious, and entirely opposed to all the data which histology, physiology, and pathology have accumulated in modern times." The "inquiry into our present means of treatment," on page 320, subdivided into the three heads of Dietetics, Hygienica, and Materia Medica, will be found a very scientific and sensible discussion of the means at our hands in combating disease. The second part of the subject is, perhaps, the one in which even our wisest practitioners must often fail. In the case of office consultations especially, the inquiries are not minute enough as to the mode of life—eating, exercise, sleeping, hours of the patients, etc.

We are tempted to linger over our notice of this book, already so well known, from the mere gratification of pointing out some of its excellences. The student or medical man who has not already profited by its complete and interesting presentation of *clinical* medicine, which is in fact the whole of medicine, will find in the letter-press, as well as the numerous and beautiful woodcuts of this work, a guide with almost the fulness of a cyclopædia, without any of its dryness. Even the "Ethics of Medicine" receive the consideration of our author, and an eloquent page is devoted to "the sense of duty and moral obligation" with which a medical man should be imbued.

We have thus spoken of this book, as if it were a new and unknown one, but this is somewhat necessary when we consider the new recruits which our ranks are constantly receiving, and who need advice in the mass of medical literature presented to their bewildered choice.

The American publishers have brought out the work in an excellent manner.

INHALATION: ITS THERAPEUTICS AND PRACTICE. By J. SOLIS COHEN, M.D. 8vo, pp. 305. Philadelphia: Lindsay & Blakiston, 1867.

WHEN a certain divine was asked why it was that he allowed the choir to sing such lively airs in his church, he replied, "*The devil has had the best tunes long enough;* it is time now that the Lord should have his share."

The last decade has witnessed a vigorous and organized determination on the part of scientific men to wrest the employment of a number of useful therapeutical agents from the hands of ignorant and unscrupulous outsiders, and to consecrate them to the service of truth and humanity. The feeling is every year growing stronger, both in Europe and America, that the quacks have had some of our best remedies long enough, and that it is time that science should have her share. It is to the influence of this spirit among the more advanced men in the profession that we owe the valuable contributions that have recently been made to the very

important special departments, of gynecology, the venereal, ophthalmology, aural surgery, the movement cure, electro-therapeutics, and the system of treatment by inhalations.

This work of Dr. Cohen is one of the many protests that have recently been issued against the sinful neglect of therapeutics, that has been so fashionable among our leaders in science. It is, at least, an attempt to find out "a more excellent way" of treating a variety of affections that have hitherto been regarded as obstinate or incurable. Although the work is mainly a collection of observations gathered from a variety of sources, and although the conclusions arrived at, on many points, are very indefinite or unsatisfactory; yet it will be, on the whole, of great service to every student of therapeutics, and must be regarded as the most valuable contribution that has yet been made on the subject of inhalations.

To the observations of other practitioners, in Europe and America, Dr. Cohen has added the results of his own experience; and although his bias in favor of inhalation is decidedly stronger than our own, he has yet presented the subject with scientific fairness, and we shall await with interest the result of his future studies.

The plan of the work is as follows: Part I. Inhalation of nebulized fluids. Part II. Inhalation of medicated airs, gases, and vapors. Part III. Inhalation of powders.

The following facts seem to be established:

1. That nebulized fluids, and also powders, penetrate into the respiratory passages.

2. That for quite a wide range of diseases of the respiratory passages, inhalations are often of very appreciable service as adjuvants.

3. That considerable further experience is necessary to settle many doubtful questions, both in regard to the utility and the method of employment of inhalations.

The record of the experiments made with the inhalation of oxygen is of especial interest and very suggestive. The plan and arrangement of the work are excellent and clear, but in his style of composition the author sometimes lays himself open to criticism. Science should always be presented in short sentences. Involved, tortuous, and unbalanced paragraphs, especially in the summing up of conclusions, are very apt to mislead and dishearten. A few short, decisive sentences will not only be more readily understood, but will also be much longer remembered.

In the pursuit of his special department of Laryngology, the author will have abundant opportunity to make further experiments with inhalations, that will, we doubt not, be of great value to science.

Our limits will not permit us to describe the work in greater detail, and we can only recommend it to all who are desirous of experimenting with this very pleasing branch of therapeutics.

INJURIES OF EYE, ORBIT AND EYELIDS; THEIR IMMEDIATE AND REMOTE EFFECTS. By GEO. LAWSON, F.R.C.S., Eng. Assistant Surgeon to the Royal London Ophthalmic Hospital; late Assist. Surgeon of Rifle Brigade. London: Longmans, Green & Co. 1867; 12mo, pp. 430.

WE have received from the author the original edition of this highly practical work. In a preceding number we took occasion to commend it to the attention of every practical surgeon, and now seize the present favorable opportunity afforded us, while acknowledging the receipt of the London edition, to reiterate this good opinion, and at the same time to refer to the very superior style in which it is issued by the publishers. Our American reprints are nominally cheaper, but our English cousins are still our masters in the typographical art.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, Nov. 20, 1867,

DR. HENRY D. BULKLEY, VICE-PRESIDENT, in the Chair.

RESULTS OF DR. QUIMBY'S METHOD OF TREATING CLUB-FEET.

DR. QUIMBY, of Jersey City, by courtesy of the Academy, exhibited two patients who had been subjected to his mode of treatment for club-feet by adhesive straps (see MEDICAL RECORD, Vol. I. p. 554). One of the little girls employed her feet without any embarrassment; while in the case of the youngest, still an infant in arms, he contrasted the difference between an original cast and the present condition.

TREATMENT OF DISLOCATED CLAVICLE BY SAME METHOD.

The doctor also exhibited a patient in whom a dislocated clavicle at the acromial end was confined in position by a similar use of the adhesive strap, along with compresses at the salient points of the injured shoulder. The adhesive band passing around the shoulder and elbow, admirably answered the purpose of immobility.

DR. FINNELL adverted to the rarity of this dislocation.

DR. QUIMBY claimed that there could be no question as to his diagnosis, which had been verified by Prof. Post. He stated that the patient had sustained the injury as a result of direct violence applied to the shoulder by a fall from a horse. He was prepared to cite another instance of the same injury which had been received by a person engaged in house-moving. The lesion, he thought, was quite easy of detection by reason of the prominence of the points in question.

DR. GARRISH thought that in the case of club-feet, the application of the adhesive strap might be made *immediately after birth*, and related a case in his own experience, where he successfully carried out this plan. For his own part, he could see but few contra-indications to a general adoption of this as a rule; he had also failed to find any very serious objections to the use of Scarpa's shoe.

DR. QUIMBY said that in the case of weak, scrofulous children, in whom the tendo-achillis had been divided at the usual time, and that, too, by experts, the condition known as "weak ankle" was not infrequent.

DEATH OF PROF. HOOKER.

DR. CHAMBERLAIN read a communication from Dr. John G. Adams, announcing the death of Prof. Worthington Hooker, of Yale College, which occurred from typhoid fever, November 6. The usual condolatory resolutions were then passed.

After an informal debate upon a question of medical ethics, which was ruled out of order, the Academy adjourned.

STATED MEETING, DECEMBER 4, 1867.

DR. ALFRED C. POST, PRESIDENT, in the Chair.

THE QUESTION OF BLOOD-LETTING.

DR. POST, by previous arrangement, opened the discussion upon the subject of blood-letting. After alluding to the antiquity of the practice—it having been in vogue among the Egyptians, Assyrians, and other nations, and resorted to by Polydorus soon after the siege

of Troy, not to mention the endorsement of Hippocrates, or its rank as a remedial agent all through the period of Roman civilization—he remarked substantially as follows: Notwithstanding its loss of reputation, partly caused by an abuse of its power, he contended that venesection was a remedy of real value, and in many cases was indispensable—in other words, that it shortened the progress of disease, and increased the prospect of cure.

Its effect upon the circulation was well marked, as evidenced by a decrease in the frequency of the pulse, a lowering of the animal heat, and a diminution in the volume of the artery. To use a conventional phrase, "the pulse rises," it becomes fuller, and the patient very often experiences relief at once. The effect of opening a vein is beautifully illustrated in peritoneal inflammation, for here the pulse being "*small*," an increase in force is more readily detected.

The doctor thought that in acute inflammations and in active determinations of blood to important organs, the blood-letting plan of treatment was of substantial value. It relieved local pain. Among the other effects he alluded to free and copious perspiration, a tendency to syncope, nausea, emesis, and sometimes convulsions.

It might be judiciously employed from infancy to old age, although in the first mentioned stage of life its application, perhaps for no very cogent reasons, was limited to the use of leeches. In advanced age great caution is required, but for the benefit of the over-timid he cited two recorded cases—one that of a man aged eighty-seven bled twice in one day, and another aged eighty, bled nine times for pneumonia—these in proof that even under this adverse condition it was not so destructive to life after all. The case of the late Dr. Cheesman [who died in 1862, aged seventy-five years, Ed.], as related by Dr. Alonzo Clark, was also to be remembered in this connection, since he was evidently benefited by a copious bleeding.

Dr. Post, to fortify his position, then related the following cases, given in brief as below:

Case 1.—A gentleman, æt. 40, low in stature, plethoric, with a short neck and much devoted to commercial pursuits, during the extreme heat of a summer several years ago, was seized with coma, convulsions, etc. When seen professionally, the bloodvessels of his face were found turgid with blood, and his whole condition naturally suggested venesection, which was accordingly performed. A copious bleeding restored him to consciousness, and probably to society. He afterward had like attacks, the second one during the extreme cold of the next winter, which were subdued by the same means; but finally, after these repeated onsets apparently excited by extreme ranges of temperature, he died of apoplexy.

Case 2.—A young clergyman, in the course of a platform speech, reeled and fell. Having a flushed face, full pulse, and great confusion of mind, he was bled, with marked and complete relief.

Case 3.—A woman, æt. 40, small and slender, with a pulse of inconsiderable force but not remarkably compressible, being seized with a severe cephalalgia, referrible to the frontal region, sent for him. He administered the usual remedies, revulsives, cold affusion to head, cathartics, but without benefit. The patient then suggested bleeding, which Dr. P. had not before entertained, owing to its apparent contra-indication. Her solicitation was backed by the assurance that previous bleedings in similar attacks had always afforded relief. The loss of something over a pint of blood from the arm verified her statement. He was subsequently called, say three or four times at long intervals, and each time the patient was bled with the same result. After several years also he was summoned at night to her bedside—she was in a state of stupor, had a wild look, was unable to speak, but significantly pointed to her elbow. A full bleeding brought relief, and since then she has enjoyed comparative immunity from attack.

Case 4.—A little over a score of years ago, before uræmia was a recognized disease, he (Dr. P.) was called to a lady with full habit in the eighth month of pregnancy; she had a vertigo, which merged into partial loss of consciousness; her pupils were dilated, her face flushed and somewhat œdematous; in fact, he was now pretty well satisfied that she was "*uræmic.*" But be that as it may, a bandage applied to her arm, as preliminary to venesection, caused fainting; still he felt, that notwithstanding the syncope, this was the course to be adopted. Dr. Delafield as consulting physician strongly endorsed this view, and as a result of their deliberation the patient lost one quart of blood with removal of symptoms. The patient was in due time delivered of a boy, who is now a husband and father. Here he thought that the lancet might be credited with *two* lives.

Case 5.—A lady, æt. 31 or 32, removing from the country to the city, in the last month of her pregnancy, with no attendant engaged, sent for him. He found her with anasarca, countenance pale, waxy, and œdematous. With a view of unloading the cellular tissue, he gave a hydragogue cathartic, and finding no symptoms of labor, he left. On the next day, however, she was taken in travail; there being great rigidity of the os uteri but little progress was made; besides, she complained of a persistent pain between her eyebrows. Fearing uræmic convulsions, he bled her freely, when the headache ceased, the us uteri relaxed, and the patient, after a natural labor, made a complete recovery.

The doctor also held to the view that even in chronic affections the lancet was not always to be avoided.

He instanced the case of a young widow once under treatment by him for a severe pain in the right hypochondriac region, along with an intense jaundice. Regarding the case as either one of impacted calculus or as a spasm of the biliary duct, he resorted to full anæsthesia, with temporary benefit, which he prolonged by anodynes. The attacks were quite frequent. Finally she passed into the hands of the late Dr. Richard K. Hoffman, by whom she was bled with marked benefit.

Another case adduced was that of a patient in the New York Hospital who was suffering from a somewhat intractable *iritis*. This was several years ago. This patient, when first seen by him, had lost no blood during the early stage, his gums had been touched, he complained of pain and impaired vision, his pupil was irregular, etc., etc. Having a firm resisting pulse, he was bled by the house surgeon under his (Dr. P.'s) direction. The inflammation then began to pass away very rapidly.

Dr. P., in concluding his remarks, cited the case of strangulated hernia at the New York Hospital upon which he had called the usual consultation of his colleagues preliminary to an operation. In the interim, however, he directed the hard, tense, and tender tumor to be covered with leeches, when spontaneous reduction took place. He also referred to the benefits of the local abstraction of blood by leeches in the case of acute pneumonia in the very young subject, and in pneumonia generally when no depressing influence was at work. Bleeding during the first twelve or twenty-four hours of puerperal peritonitis, and by this he meant the sporadic variety occurring in private not public practice, he also regarded as beneficial, notwithstanding the small pulse and the first difficulty to get a flow of blood.

Dr. Anderson referred to the change in professional

opinion regarding this matter, which would be more obvious by contrasting a period twenty-five or twenty-six years ago with the present time. He remembered having read the work of Dr. Armstrong on fevers, which very strongly impressed him. Venesection in this treatise was much praised, and it had occurred to him that following up the bleeding with anodynes would be eminently philosophical. While of this way of thinking a gentleman, "a full and hearty liver," sent for him. The patient had great respiratory oppression, but no pneumonia—bleeding at once relieved him. In the case of Dr. Cheesman it would be proper to note, that notwithstanding the very happy result, much more blood was lost than was originally intended, since the slipping off of the bandage allowed the bed to become quite well ensanguined before the discovery was made.

Dr. Woodhull reminded the Academy of the case of Dr. Francis, deceased, who was bled to about the amount of eighteen ounces for the relief of laryngitis.

Dr. Foster also reverted to the time when bleeding was usual. He was quite certain that he had cut short the progress of an acute pneumonia, some three, four, or five days, by the opening of a vein and a reliance upon diluent drinks. In those cases where bleeding was omitted—for, even in those days, all did not bleed—he inclined to the view that the percentage of recovery was less. He had himself lost two pounds of blood for a pleurisy, and with immediate relief. The doctor then described a fever of congestive character which prevailed in 1837, in a country village, previous to his taking up his residence in this city. In these cases, venesection evidently was of benefit.

Dr. Garrish thought that discrimination in the use of the lancet was necessary—that in certain cases it was absolutely essential, while in others its effect could not but be pernicious. He regarded depletion in acute inflammation of the eye as a remedy of great value.

Dr. Peter Van Buren remembered having himself been bled by a distinguished physician of Albany, now deceased, twice in a short interval, for a threatened inflammatory disturbance. A low fever, of a typhoid character, proved that the operation was uncalled for.

At the beginning of his professional career, it was thought impossible to initiate the treatment of pleuritis without a resort to blood-letting. In such cases, the respiration did certainly become quite free. He also alluded to the benefit accruing from venesection in two cases of puerperal convulsions, before the days of chloroform.

Dr. Worster gave in his testimony regarding the application of leeches between the shoulder-blades—especially in the case of young children suffering from pneumonia of a grave type. He was in every sense well pleased with the result.

Dr. Sayre was cognizant of a case where leeches were applied between the shoulders, and the child in consequence died. This had made a strong impression on him. Oiled silk jackets, poultices, etc., he regarded as much safer and more serviceable.

Cases requiring prompt bleeding he regarded as quite rare. He did not wish to be understood as saying they never occurred, since he had himself carried a lancet in his vest pocket for fifteen years and had used it three times.

A broad distinction existed between local depletion and the abstraction of blood from the general circulation. The effects were quite different. For his own part, he could not see why girdling the arm and the leg on the opposite side for ten or fifteen minutes at a time, and then alternate with the opposite limbs, should not, by the withdrawal of a certain amount of blood from the general circulation, answer the object of the practitioner much better, and with less risk. For, in these instances, the blood is not lost, but temporarily withdrawn—its mission to nourish and repair has only been suspended.

The change in our modes of treatment, he remarked, was due, not to popular prejudice, but to the increased information of medical men. The starvation and the lancet plan had gone out of date—all were beginning to believe more in good food and good air.

Dr. Woodhull would hesitate to bleed except in sudden apoplexy. Some twenty-five years ago, it was quite difficult to get women to do without being bled once a year. He had, however, converted some over to his views, and they had invariably admitted that their health had improved after the discontinuance of the practice.

As regarded puerperal eclampsia, he guarded against it by careful watching of his patients previous to their accouchement. A few fortnightly visits would often save much vexation and anxiety.

Dr. W. was of opinion that in discussing these and kindred subjects we did not keep sufficiently well in view, the difference between patients in the country and those in the city.

Dr. Richards, after a few remarks by Dr. Van Buren concerning a change of type in disease, asked whether it might not be a change of opinion, and for the purpose of giving the junior members of the Academy an opportunity of expressing their views, he moved that the discussion be resumed at the first opportunity.

Dr. Griscom, in seconding the motion, remarked that the very important element of physical and chemical changes as affecting the character and condition of the blood, had been entirely lost sight of during the discussion of the evening.

The motion prevailed and the Academy adjourned.

NEW YORK MEDICO-LEGAL SOCIETY.

Stated Meeting, Oct. 22, 1867.

Dr. T. C. Finnell, President, in the Chair.

DUTIES OF A MEDICAL WITNESS IN CASES OF MAL-PRACTICE.

Dr. James J. O'Dea, in continuation of the discussion upon the above subject, offered the following remarks:

He recommended in the first place, that when a physician is asked to give testimony in a case involving the reputation of a fellow practitioner, he should consider the following questions: *Does my education* (taking the word in its broadest sense) *qualify me to pass judgment in such a case? Am I sufficiently unbiassed to be able to give a fair, unprejudiced testimony?* Conceding his satisfaction as to his qualifications in this respect, he answers these two questions in the affirmative; he might then proceed to give the disputed subject his serious and careful attention, pursuing the following order: He should examine accurately the facts upon which his opinion is to be based, cautiously abstaining from a conclusion until every relevant point is investigated, questioned, and found reliable. Now, this is the test of "a competent witness." In the performance of this duty, if not before, the value of the preliminary questions already mentioned, will become evident. It will then appear that not every man has the requisite patience judicial quality of mind, or logical training in weighing the value of evidence, in separating what is essential from what is non-essential, what is reliable from what is unreliable.

As a digression, he might refer to the fact that very

often there are at least two opposing medical witnesses in trials having a medico-legal bearing, and sometimes each so identifies himself with the cause of the side on which he is engaged, that, in the witness-stand, the medical evidence is contradictory to an astonishing degree. Why is this? Some explanation is not difficult. Each has considered his own side of the question, and that only. Neither gets possession of the facts common to both sides. Neither starts from a common ground. They have either never consulted together, or the consultation has been held in that formal and ridiculous manner out of which nothing comes, and which, even in the ceremonious old days of three-cornered hats and powdered wigs, was made the theme of many a jest by caricaturists and satirists.

But to return, let us suppose a case in reference to the more immediate subject in hand. Take the simplest. A surgeon is sued for shortening of a leg, the result of fracture of the thigh bone. What is the duty of the medical expert in approaching such a question? First, he would repeat, he should decide *on his own competency*. After that, he may examine the history of the injury, its nature, the period at which the surgeon was called in, the mode of treatment adopted, the care and conduct of the surgeon in his dealing with the case, and equally, the conduct of the patient during treatment. He will take his measurements of the limb, comparing the shortening with what he has witnessed in his own experience, and learned from that of others. He will do all this that he may be able to give an intelligent answer to questions such as the following: Was the limb properly treated? Was the conduct of the surgeon in relation to his patient such as to lead to the conviction that he used all necessary and usual precautions to insure as sound a limb as the circumstances permitted? He did not say these are the questions that will be asked upon the stand, he did but think they contained about the pith of the whole matter.

Now let us place our medical expert in the witness-stand and ask ourselves what are his duties there. They are many, including those to science, to himself, and to the physician whose reputation is on trial. In respect to science, he stands in the relation of an advised and independent exponent of its most modern, most advanced ideas. One of the most important of his duties is to be independent and unbiassed. No matter on what side he may be engaged, he should strive, above all else, *never to be a partisan*. He should be calm and self-possessed. Few men of any profession enter a witness-stand without a degree of nervousness varying according to individual temperament. Some can easily subdue this, others partly, and again others not at all. These last should avoid such a position. A good deal that is wise has already been said during the progress of this discussion on the best way to answer the questions of counsel; so, leaving this part of the subject, he will conclude by offering a few words on the duties to the accused practitioner. He should have the full benefit of every doubt. The medical expert should shield him and defend him by every means in his power consistent with truth and a beneficent justice. It is a good rule to adopt—and so far as he had considered the matter, it admits of no exception—never to pronounce an opinion adverse to the treatment of a case unless it displays some fault which can only be attributed to gross and culpable neglect. That one physician should condemn another for "an error of judgment," is so pedantic, so ultra-dogmatic, as to seem almost incredible if frequent experience did not teach otherwise.

After some further discussion on the part of the Society, and a liberal interchange of individual opinion, the Society adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, Nov. 13, 1867.

DR. H. B. SANDS, PRESIDENT, in the Chair.

REMOVAL OF STONE BY DILATATION.

DR. HAMILTON presented the bladder, urethra, with the left ureter and kidney attached, etc., taken from a woman, of whose case he presented the following history:

Harriet James, a mulatto, aged thirty-nine years, born in Virginia, was admitted to Charity Hospital, Blackwell's Island, August 21, 1867, suffering with a stone in the bladder. She was a married woman, and had borne seven children. She had been blind from early infancy. During the last four years she had passed several calculi, some of which were of the size of an almond. At the time of her admission she was laboring under chronic cystitis, and suffered great pain, accompanied with an almost constant desire to urinate. The stone was felt with the sound, pressing snugly against the neck of the bladder. It could also be felt distinctly with the fingers through the walls of the vagina.

Sept. 5, 1867, in presence of a number of medical gentlemen and students, I removed the stone by the method of dilatation. Rapid dilatation was made rather than slow dilation, as has usually been practised and recommended, because the irritability of the bladder and urethra was such that they would not have tolerated the presence of an instrument or of any foreign substance for any length of time.

The patient having been placed under the influence of ether, I introduced a Weiss' female urethral dilator, and in about five minutes opened the blades nearly one inch. I then closed and withdrew the dilator, and introduced successively several sizes of gold and hollow india-rubber bougies. The last had a diameter of just one inch. Withdrawing this, I now introduced the forefinger of my right hand easily, and felt the stone. Withdrawing my finger, I carried in a medium-sized lithotomy forceps, and seized the stone; but it was so brittle that it crumbled under the pressure of the instrument, and I brought out only a portion. I removed a few other fragments with the forceps, and the remainder I washed out with warm water, thrown in with a large syringe. With my finger I could now feel the whole interior of the bladder, and I found that no particles were left.

During the operation a few drachms of blood escaped from the lacerated mucous membrane of the urethra. I could also feel the urethra contract sensibly, but not suddenly or spasmodically, upon my finger. The patient was then returned to bed.

During several weeks preceding the operation she had been kept constantly under the influence of opiates, I was informed, to appease her suffering. These it was found necessary to continue, as the pain in the bladder had not much subsided after the removal of the stone. It was remarked, however, that she retained her urine after the operation as well as she had done before; that is, she was able to hold it an hour or more, and then the desire to urinate became so great that she was compelled to rise and evacuate the bladder. In rising no water escaped until she sat upon the vessel, nor did any urine escape involuntarily in bed, until a few days before death. Injections of morphine and of nitrate of silver were employed to allay the irritability of the bladder, but to no purpose.

On the 20th of September a diarrhœa commenced, which passed soon into dysentery, and this continued until she died. Her death took place October 2, 1867, about one month after the operation was made.

Autopsy.—The ureters and the pelves of the kidneys were greatly dilated, and were filled with pus and urine. The walls of the bladder were greatly thickened, and the inner surface was lined with masses of lymph, arranged in laminæ, with portions hanging in shreds. The urethra remained dilated sufficiently to admit readily the forefinger, but it was not as dilatable as at the time of the operation.

Dr. Hamilton, in connection with the case, remarked that he had operated for lithotomy five times successfully, but that this was the only one in which dilatation had been employed. He was of course unable to draw from it any conclusions as to the advisability of the latter method. He was not sure but that she held her water in some measure because of the swelling, but he was confident that the circular fibres were not paralyzed; the fact, however, that it was still dilatable after death did not rule out the possibility of her having incontinence afterward, in case she had lived. The fact that the chronic cystitis was not relieved by the operation was a recommendation for an incision into the viscus. He reminded the members that Dr. Emmet had recently advocated the creation of a vesico-vaginal fistula, in cases of chronic cystitis, the idea being to relieve the bladder by an incision into its walls. The subsequent closure of the fistula was comparatively a small matter.

In answer to a question from Dr. Van Buren, he stated that there was no particular change after the operation, save a slight amelioration of the bladder symptoms, and that as far as any evidences of pyelitis were concerned, there was nothing found.

Dr. Van Buren remarked that the failure of the operation to relieve the inflammation of the bladder suggested to his mind the possibility of the existence of pyelitis, and purulent urine coming down from the kidneys into the bladder, thus keeping up an irritation independent of the stone.

Dr. Sands remarked that a few years ago he removed a stone from a pregnant woman. She had symptoms of stone for several months only, and at the time he was consulted she was suffering from symptoms of very severe cystitis. The tenesmus of the bladder was almost constant, and the discharge of purulent urine, loaded with phosphates, was very profuse. The question came up as to the expediency of performing the operation at once, when it was decided in the affirmative, and the stone was removed in accordance with the suggestion of Dr. Emmet. The incision was made through the vagina, and the calculus extracted with very little trouble. The stone was a little over an inch in its longest diameter. He was satisfied that, at the time of the operation, the coats of the bladder were somewhat altered. The vesico-vaginal fistula was immediately afterward closed by six silver sutures, which were removed on the eighth day. The cystitis was arrested at once, and all vesical tenesmus ceased. She was afterward confined, in due time, and everything went on well.

Dr. Jacobi asked Dr. Hamilton if the membrane lining the bladder, in his case, was of recent origin.

Dr. Hamilton believed that it was both recent and old.

Dr. Jacobi remarked that, if it could be settled that it was of recent date, it might be assumed that the deposit was the result of a diphtheritic exudation, which might have had a significant relation to the dysentery from which the patient suffered.

Trichiniasis.—Two deaths from Trichiniasis have been reported in St. Louis.

Correspondence.

MEDICAL MATTERS IN PARIS.

(from our own correspondent.)

To the Editor of the Medical Record.

Sir—To-day celebrates the closure of the Exposition; to-morrow will witness the reopening of the Ecole de Médecine, and the beginning of the long medical year.

In Paris, the ceremonies of the year are reserved for its close as in Italy, while in England, as in Spain and Portugal, whatever solemnities are deemed fitting to dignify the old critical days of the scholastic season are observed at the moment of its recommencement. *L'Union Médicale*, of Paris, in reviewing the celebrations held at the different schools, greatly commends the simplicity of the English, who quietly assemble at the numerous "head-centres" of instruction, listen to a regulation address, and immediately set to work at their studies; whereas, in Madrid and Lisbon the affair is made a state occasion, honored by the presence of the king and highest public functionaries. It is pomp *versus* utility, says Dr. Simplice, and the contrast is manifest even in the themes chosen by the professors for the address. That of Mr. Graily Hewitt, for example, at the University College in London, was entitled, "The Therapeutic Utility of Alimentation," while the discourse of Professor Alonzo at Madrid was devoted to an elaborate exposition of "The Benefits of Instruction."

In Italy, the illustrious Professor Tommasi celebrated the close of the year of official instruction by a retrospective review of the most important clinical facts that have presented themselves to his observation since its commencement. M. Tommasi energetically insists on the sufficiency of clinical study to meet its own legitimate ends, and protests against the prevailing tendency to accept the ideas of Chomel and degrade it into a simple stepping-stone for pathological anatomy. "Clinical study alone has established the causal relations between articular rheumatism and endocarditis, between alcoholism and arthritis on one side, and endo-arteritis on the other, between different species of constitutional infection and an increase in the volume of the spleen, between syphilis and certain special neoplasias of the connective tissue, between scarlatina and croupal inflammation of the pharynx and kidneys."

You remember that Continental physicians (not including, however, the French) are agreed to denominate all inflammations attended with fibrinous exudation croupal.

EPILEPSY DEPENDING UPON PREMATURE OSSIFICATION OF THE CRANIAL SUTURES.

Among other interesting facts quoted from his clinic, Tommasi signalizes a case of epilepsy in a child, dependant upon premature ossification of the cranial sutures, especially the spino-occipital. This cause of epilepsy has been specially signalized by Virchow. In Tommasi's case, the disease was greatly ameliorated by the use of nitrate of silver, but it is difficult to imagine why.

CONCERNING PTISANS.

The use of ptisans is so widely spread in France, where cold-water drinking is considered at once an imbecility and a crime, that their selection becomes a matter of considerable importance. M. Miquel (de Tours) has just published some suggestions on the drinks most suitable in typhoid fever that might be not altogether useless at home. He proscribes all amylaceous

and sugared mucilaginous drinks, especially those containing vegetable acids, and all fermentable preparations, on the ground that they increase the secretion of bile, and the confluence of the intestinal eruption. Therefore, instead of lemonade, currant jelly, gum and barley water, M. Maquel recommends infusions of linden and orange leaves, chamomile and mignonette; also water flavored with a few drops of coffee, tea, brandy, or rum. In preparing rice water, mixed with decoctions of poppy heads, the physician of Tours directs that the rice be not added to the decoction ready made, but only allowed to remain in contact with it long enough for the water to extract the astringent principle of its rind.

DYSPEPSIA AND ITS TREATMENT.

M. Malherbe, of Nantes, publishes some reflections on a subject calculated to interest the inmost heart of every American—on the treatment, namely, of dyspepsia. Considering that, in our favored land, all the blessings of liberty are impotent to save us from the grasp of this foul fiend, and that nearly every one of us has either had dyspepsia, or actually suffers from it, or is destined to suffer in the future; no suggestions on the subject can afford to be lost. M. Malherbe strongly recommends the use of pure hydrochloric acid in all cases of the atonic form of the disease. He considers this substance to act as a stimulating tonic, which facilitates stomachal digestion by assisting to dissolve albuminous substances; by regulating the secretion of gastric juice; by remedying constipation in virtue of an exciting action on the intestine; finally, by a tonic action on the general economy. In various cachexias, even advanced tuberculosis, this medicine is found to render good service. I have myself had an opportunity of testing the truth of this observation, especially at Lariboissière, in the wards of M. Hérard. He is enabled, by means of this acid, to greatly relieve the various dyspeptic symptoms (among which frequent vomiting is not the least painful) which torment the last days of his numerous consumptive patients.

It is recommended to associate wine of quinquina, calumba, or rhubarb, and some preparation of opium with the hydrochloric acid. The following is the formula employed at the Hotel Dieu of Nantes:

Wine of Quinquina . . .	100	grms.
Syrup Thebaic	30	"
Pure Hydrochlor. Acid .	1	"

Mix.

The dose is from two to six teaspoonfuls a day. To relieve the gastralgic pain to which many dyspeptics are martyrs, M. Miquel suggests the administration of a concentrated opiate, combined with a bitter, which serves to correct its injurious effects. The following is his formula:

Syrup of Bitter Orange Peel,	}	āā q. s.
" Morphine		
" Ether		

Mix.

Where the pain comes on principally *before* eating, it is advisable to administer a narcotic or etherized draught about a quarter of an hour before meals. It is M. Hérard's practice to give his patients ten drops of Sydenham laudanum immediately before, and one grm. of pepsine immediately after eating. This treatment entirely relieved the pain, and stopped the vomiting in the case of a woman, who subsequently died from the effects of a diarrhœa maintained by deep tuberculous ulcerations of the intestines, and with whom the mucous membrane of the stomach presented the signs of such an intense arborescent injection, mingled with yellow and slate-colored spots, as really merited the title of gastritis.

ARSENIC IN CEREBRAL CONGESTIONS.

Therapeutics does not constitute at present the most fashionable subject of meditation in the medical world, so much the more, therefore, do I glean studiously all indications of experiment in this direction. M. Lisle has just read a note before the Academy on the advantages of arsenic in the treatment of intercurrent cerebral congestion among the insane. M. Lisle considers hallucinations to be, not a symptom, but a complication of insanity, and always dependent upon congestion, consequently always to be treated by arsenious acid. He claims to have cured 131 patients out of 193 by the use of this medicament, and to have markedly ameliorated the condition of twenty-nine others. If the facts cited by M. Lisle are trustworthy (and there is no reason to suppose they are not) they are in striking opposition with his theory. According to the analogy of its action in all other cases, arsenious acid should be considered as an eminent tonic of nutrition, regulating the life of the capillaries, perhaps, in several ways, but by no means tending to disgorge them of unseemly congestion. At the hospital Beaujon, M. Montard Martin told me that he employed arsenious acid with considerable success against cholera in the last epidemic, and there seemed reason to suppose that the capillary circulation of the surface was restored or stimulated by this potent drug in a manner to relieve the deadly visceral congestion. Moreover, as the editor of the *Montpellier Médicale* remarks, it is far from proved that hallucinations are connected with congestion of the brain, a condition not indicated merely by some redness of the face and brilliancy of the eyes. According to the ideas of Luys in his recent brilliant researches into the minute anatomy of the cerebro-spinal system, hallucinations occur when the thalami optici, instead of simply receiving impressions from without and irradiating them to the periphery, set up an independent action, and originate impressions in the recesses of their own structure. This might occur whether they were excited by congestion or their normal functions perturbed by anæmia.

For those who have not read M. Luys' book, it may be necessary to explain that many of his views on the structure of the brain are quite original. The particular theory to which I have just referred rests on another, purely anatomic, namely, that all sensitive fibres proceeding from the posterior and lateral columns of the spinal cord, are destined to terminate in the thalami optici, which constitutes the first receptacle and halting place for impressions received from the world without. Here the crude impressions are elaborated and ultimately radiated to the vesicular matter of the convolutions along the converging white fibres that apparently proceed from the surface to the base of the brain. These are not, as generally affirmed, the mere continuation of the fibres from the cord, but new ones, deriving their origin from the thalami optici themselves.

THE CHARACTERS OF CEREBRAL SOFTENING.

In this connection it is natural to mention the essay in the *Archives de Médecine*, written by Proust, on softening of the brain. The dominant idea resulting from the researches of this distinguished young physician, is the separation of softening (*ramollissement*) both from encephalitis and hæmorrhage. Encephalitis determines a neoplasia, or is equivalent to it, precisely as inflammation generally involves the idea of exudation.

Hæmorrhage usually results from the rupture of a

capillary aneurism. But *ramollissement* is a necrobiosis, essentially the same as gangrene of the limbs, and its phenomena only differ because the tissues involved are withdrawn from the action of the air. M. Proust, however, reserves the name necrobiosis for a molecular destruction of tissue, and to its destruction *en masse* assigns the term necrosis.

The death of the cerebral substance depends upon obstruction of the capillary circulation, however caused, whether by a thrombus, an embolus, stricture of the cerebral arteries, fatty degeneration of the capillaries, thrombus and phlebitis of the sinus, etc. In these cases, there may be produced either a condition of anæmia or of hyperæmia. If an obstacle to the circulation be situated in the sinus, there is always hyperæmia; obstacle in the capillaries occasions rather anæmia. The first produces the red, the second the white softening. Hyperæmia of the parts surrounding the focus of softening is easily explained by the collateral fluxion in branches of the vessel whose tension has been increased by the obstacle to the circulation. Hyperæmia of the centre of the infarctus is more difficult to account for, and M. Proust only suggests with some hesitation, that it may be due to some action on the part of the vaso-motor nerves, or the result of a functional alteration of the capillaries.

The white coloration is rarely observed, but occurs occasionally in cases of general cachexia, as in the case of cancerous patients.

The red coloration may be uniform, and is then more marked at the periphery; or spotted, and then results from little hæmorrhages arising from the rupture of a great number of capillaries.

Diminution of the consistence of the part is appreciable from the second day. The tissue has a trembling jelly-form appearance. Then the part becomes tumefied, it is softer, the furrows separating, the convolutions disappear, and by the third or fourth day it has become reduced to a diffluent paste.

The first phenomenon detected by the microscope is the appearance of fatty granulations in filtering the tissue. These have been observed at the end of twenty-two hours by Charcot, and thirty-six hours by Prevost and Cotard. Then granular bodies succeed to these fatty granulations and accompany them. According to Bouchard these granular bodies consist of agglomerations of fatty granulations.

Transformations speedily take place, corresponding to what has been described under the name of chronic softening, *plaques jaunes*, cellular infiltration. The coloring matter of the blood transudes through the walls of the capillaries; that already extravasated becomes converted into yellow granular amorphous masses, or else into reddish oblique rhomboidal crystals, the hæmatoidine of Virchow.

Later, a neoplastic effort sets up, and a tendency to cicatrization appears; the pia mater contracts adhesions with the bottom of the excavation that has been formed by resorption of disorganized tissue, and across this excavation are extended laminæ of connective tissue. The tissue surrounding the softened part becomes slightly indurated in virtue of a proliferation of nuclei and cells. This last is analogous to the formation of an eliminating membrane around a patch of gangrene in a limb.

Prévost and Cotard, under the direction of Vulpian, have made a number of experiments on the production of foci of *ramollissement* by injection into the arteries of powder of lycopodium or tobacco. They succeeded in simultaneously provoking infarctus in the brain the spleen, and the kidneys, were able to observe the apparition of fatty granulations and granular bodies, and determine the formation of *plaques jaunes*.

Although the opinions have been refuted which attached softening to inflammation, on account of a mistaken idea that the yellow degeneration consisted of pus, Proust admits that certain analogies exist between the two affections, especially in the formation of the zone of proliferation. Further, that it is impossible to say that hæmorrhage and softening exercise no mutual influence on each other; on the contrary, the first tends to destroy the tissue directly, and to cut off its nutrition, or, on the other hand, the second, by withdrawing from the capillary walls their normal support, predisposes them to yield to the pressure of the blood.

The influence of atheroma upon the production of hæmorrhage is of course unquestionable. I had an opportunity of observing a remarkable illustration in an autopsy recently performed at La Charité. The aorta was atheromatous from its base to a point below the cross; the carotids were sprinkled with atheromatous patches, but arrived at the brain, the internal carotid showed complete degeneration. The same was true of the branches of the basilar artery. In this brain, sections in any direction revealed a punctuated injection caused by rupture of the capillaries, and in the middle lobe of each side, adjoining the thalami optici, existed a small focus of hæmorrhage.

Truly yours,

P. C. M.

PARIS, Nov. 8, 1867.

THE NECESSITY OF EXECUTIVE SESSIONS FOR THE DISCUSSION OF ETHICAL POINTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—As I have always noticed that whenever a point involving personal notoriety is likely to be discussed before the "Academy," the would-be martyr takes the precaution to come duly supplied with reporters representing the secular press, would it not be well to enforce the rule of exclusion by at once going into Executive Session? We have already had two rather singular coincidences of the presence of reporters from a paper or two of known animosity to the Academy, when it was desirable that an appeal to the public should not be lost for the want of a medium of communication or a sensational rhodomontade. How should these representatives of the press be present then, and never before or since? Simply, because when one desires to play the Spartan, with his back to the rock, he is determined that his pluck shall somehow or other be appreciated.

Yours truly,

G.

NEW YORK, December 2, 1867.

New Instruments.

THE UTERINE APPLICATOR.

By F. B. LAWSON, M.D.,

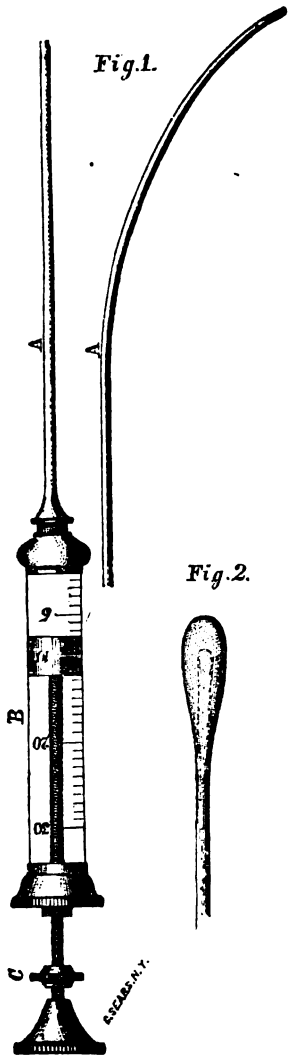
OF NEW YORK.

THE object of this paper is to furnish the medical profession with a description of an instrument, devised by myself, for applying caustic and astringent solutions to concealed mucous surfaces.

I will not question here the propriety or impropriety of this mode of treatment in a certain class of diseases affecting these surfaces, for I am satisfied that this interesting point is already decided; it is the manner of applying them that should engage our attention.

By the usual methods, we all, no doubt, have experienced many difficulties, exposed the patient to many dangers, and often failed in obtaining good results, simply because the surfaces were unevenly touched—too severely cauterized, or not cauterized at all. To obviate these difficulties, and to enable me to apply these preparations to the proper surfaces, I was induced to adopt this new method, and the results, so far as I have progressed, have been remarkably favorable. It gives me perfect command of the caustic, which can be used of any strength; enables me to apply solutions evenly and thoroughly to any surface, as the laryngeal, pharyngeal, and the eustachian tube, to the mucous membrane of the male and female urethra; and even to that of the uterus, which, by the usual methods, is frequently inaccessible, unless the parts are previously dilated.

Fig. 1.



This instrument, which I have denominated a *caustic applicator*, has a nozzle, Fig. 1, A, which is a conical, flexible silver or platinum tube, the size at its bulbous extremity of a No. 2 bougie, at its base of a No. 3, is 7½ inches in length, and is attached to a glass syringe, B. The piston of this syringe works by means of a screw through the nut C, which is attached or not to the cap as the operator may choose, but in other respects it is like the improved subcutaneous syringe, except that the metal below the plunger is of pure silver.

Fig. 2.

The steps necessary to prepare the instrument for use are these:

1. The syringe is to be completely filled with whatever solution is required, and the liquid forced to the end of the tube.

2. A piece of cotton, more or less, according to circumstances, is to be carefully and securely wound round the end of the nozzle, so as to form a bulb (see Fig. 2), which must be thoroughly wet in warm water immediately before being used.

3. The nozzle is to be bent to suit the part on which the operation is to be performed.

To use the instrument, however, after being thus prepared, some little dexterity is necessary, which is soon acquired by practice. The cotton bulb is now applied to the part to be cauterized, a quantity of fluid sufficient to saturate it is to be injected, when it can be used as a swab, and should be moved from within outwards. The piston at the time of injecting the cotton should work through the nut (Fig. 1, C) attached to the cap, and by observing this precaution, the operator, with a little experience, and with the assistance of the gauge, can use whatever quantity of fluid he desires.

This instrument possesses numerous advantages, *the most important of which are these:*

1. It gives the operator perfect command of *whatever preparation he wishes to apply.*

2. It permits of these applications being made to surfaces that are for the most part not readily accessible by the ordinary means.

3. The nozzle being flexible, it is appropriate for all concealed mucous surfaces, and therefore it does the work of many instruments.

4. It applies clean caustic on a clean swab, and cauterizes the precise spot affected thoroughly and evenly, and removes all coagulable materials.

I have used this instrument in the pharynx, for which it is peculiarly appropriate: in the uterus, where I employ it frequently, and for which organ it was originally intended; in the male urethra, in cases of gonorrhœa and gleet, and in all with ease, safety, and decided benefit.

I trust that the profession will find this instrument as useful and valuable, or more so, than is here claimed. In some future issue I may present details of a few cases of uterine disease treated by this applicator.

87 West Thirty-first street.

Medical Items and News.

The Transactions of the American Medical Association, Vol. XVIII., may be obtained of Dr. H. D. Bulkley, 42 East Twenty-second street, by those subscribers who have not yet been supplied. Non-subscribers are also entitled to be furnished at the usual rate of $5.00. We trust that every practitioner of medicine will feel it his duty to sustain the enterprise, and thus relieve the embarrassments of the Publishing Committee.

The Late Professor Robert Watts, M.D.—At a meeting of the Trustees of the College of Physicians and Surgeons in the city of New York, held 18th of November, the registrar having communicated the decease of Robert Watts, M.D., late Professor of Anatomy in the College, on the 8th day of September last, in the city of Paris, the following resolutions were unanimously passed:

Resolved, That by the decease of Professor Watts the College has sustained a loss of one of its most accomplished and successful teachers, whose untiring zeal and devotedness to its interests have largely contributed to its steadily advancing prosperity. For nearly thirty years Dr. Watts had occupied the chair of Anatomy, and taught this most important branch of medical science with acknowledged ability and success, and to the great advantage of the numerous classes of students who have attended upon his instructions.

Resolved, That this Board not only desire to commemorate the loss sustained by the College, but also to express their deep sense of the excellence of Dr. Watts' character, and the heartfelt sorrow they experience in this bereavement.

Resolved, That a copy of these resolutions, duly authenticated by the signatures of the president and registrar, be communicated to the family of the deceased, with the assurance of the sympathy of this Board in the affliction they have sustained.

Resolved, furthermore, that these resolutions be published in the medical journals of the city.

Gurdon Buck, *Registrar.*
Edward Delafield, *President.*

Death from Chloroform.—A death from chloroform is reported in Chicago. The cause is referred to simple asphyxia from the toxic effects of the article, although portions of cracker, of which the patient had partaken shortly before the administration of the anæsthetic, were found in one of the bronchial tubes. The chloroform was pure, and but an ounce was administered. Every means to restore the patient was resorted to without avail.

A Doctor's Bill in the Reign of William III.—In the diary of Sir Thomas Rokeby, justice in the Court of Common Pleas in the reign of William III., just published, occurs the worthy valetudinarian's doctor's bill for only two months, October and November, 1697:—"Purging pills, 2s.; leeches, 6d.; aperitive ingredients, 1s. 6d.; hysticricke water, 2s.; a purging bolus, 1s. 6d.; purging pills, 1s.; Gascan powder, 4s.; vermifuge pills, a box, 3s. 4d.; a purging bolus, 1s. 6d; purging pills, 1s.; cephalick drops, 2s. 6d.; an hysterick julep, 3s. 6d.; hysterick pills, 85, 6s. 8d.; a vomitive potion, 2s. 6d.; a stomattick cordial, 2s.; a cordial potion, 1s. 8d.; vomitive salts, 3 doses, 1s. 6d.; the hysterick julep, 3s. 6d.; Mithridate, 1s.; the vomitive potion, 2s. 6d.; vomitive salts, 1s. 6d.; the hysterick pills, 6s. 8d.; the hysterick julep, 3s. 6d; sal-armoniac, 6d.—2l. 17s. 10d." Spite of this drenching, to which he had to subject himself, he lived to the age of 67.—*British Medical Journal.*

Scotch Munificence.—Subscriptions, varying in amount from 25*l.* to the large sum of 5,000*l.* continue to be paid in for the new buildings on Gilmore Hill, for the University of Glasgow and Hospital, and the total already amounts to the enormous sum of 101,600*l.* 19s. 2d.—*British Medical Journal.*

Dr. D. S. Young has been appointed to the Chair of Surgery in the Cincinnati Medical College.

Dr. E. S. Connor accepts the Chair of Medical Chemistry in the Medical College of Ohio, vice Dr. Roberts Bartholow, resigned.

Dr. Henry P. Sartwell, eminent in scientific circles, died at Penn Yan, N. Y., Nov. 16th ult.

Colonel Warren Webster, Surgeon United States Army, has been relieved from the Army Medical Board, in New York city, and assigned to duty as the Medical Director of the Military District of Texas. Colonel Webster had charge of David's Island Hospital during the war, and earned a high reputation for the order, discipline, and general good management of the important post.

M. Nelaton has resigned his chair as Professor of Clinical Surgery. The reason assigned is, that, in addition to his previously immense practice, the recent death of Jobert de Lamballe and Velpeau has put upon him a large amount of work. We have heard M. Nélaton's professional income, from private practice, his positions as surgeon to the Emperor and professor agrégé, estimated at $126,000 per annum. It is said that the anatomist, Sappéy, will succeed him in the clinical chair.—*Medical Gazette.*

The Scarcity of Dissecting Material in London is the cause of much complaint on the part of medical teachers and students. It is supposed to be due to the suppression of the remuneration which was formerly bestowed upon undertakers for the increased trouble of delivering over the bodies to the proper authorities.

The Second Volume of the Sanitary Commission's publications, edited by Prof. A. Flint, is in press. It treats upon medical topics connected with the late civil war.

Surgeon H. F. McSherry, U. S. N., died at sea, October 1st ult., on board the U. S. Steamer *Wyoming*, and was buried at Singapore October 3. He entered the service June 23, 1860, and was promoted to surgeon September 22, 1863. In the early part of 1864, he was on duty at the Naval Hospital, Memphis, Tenn., but was detached and ordered to the *Dacotah*, afterward serving in the North Atlantic Squadron. He was ordered to the *Wyoming* March 18, 1865, and at the time of his death was a passenger, condemned by a medical survey.

The Prize Essay on Physical Longevity—by American Popular Life Insurance Company. This company offered some time since a prize of $500 for the best essay upon this subject. Two communications of the number presented were so meritorious, and it was so hard to decide the question of superiority, that a prize was given to each. The successful authors were Dr. J. H. Griscom, of New York, and Dr. J. V. C. Smith, of Boston.

A Grandmother at Twenty-eight.—An old practitioner who is giving the reminiscences of his medical experience in the *Gazette Médicale de Lyon*, enumerates among them the case of a young girl in his vicinity, who became the mother of a healthy child at the age of fourteen. The child was a girl, and in her turn became a mother at fourteen years of age. The young grandmother, he says, is still hard at work in her village, and is very proud of her title to a unique fame as a grandmamma at twenty-eight.

Sir William Lawrence.—The council of the College of Surgeons have resolved to purchase a bust of their late colleague, Sir William Lawrence, to be added to their collection of Surgical celebrities which ornaments the hall and staircase of the college.

Trichiniasis in Berlin.—Trichiniasis has appeared in Berlin; seventy cases have been already reported, of which two have proved fatal.

The Weight of Trichinæ.—Professor M. Weissner, of Vienna, has computed, that it must take thirty-five millions of trichinæ to equal the weight of one drachm.

A Painful Accident.—Dr. Weber, Professor of Surgery at Heidelberg, and two of his assistants, recently died of diphtheria under the following circumstances:

It was necessary to perform tracheotomy in a case of diphtheria; and in the course of the procedure a clot of blood got into the trachea. M. Weber attempted to extract it by suction in the absence of a proper instrument, and, failing to do so, his two assistants also attempted. All three of them died within six days of each other!

Miasmatic Fevers treated by Chloroform internally.—Dr. Geo. F. Brickett of Chicago (*Chicago Medical Journal*) gives some interesting results attendant upon the administration of chloroform internally. He was led to make use of the article on the recommendations of Prof. Merrill, of this city. Six cases of cure by this agent are recorded. The dose was a fluid drachm, and in every instance the patient, instead of having a chill, went quietly to sleep.

Dr. Roberts Bartholow has been appointed Professor of Materia Medica and Therapeutics in the Medical College of Ohio.

M. Claude Bernard has been raised to the rank of Commander of the Legion of Honor.

Dr. Robert Jessop, formerly of Ireland, died at Mount Erie, Ill., October 30, in the 67th year of his age.

Original Communications.

A SPRING AND SELF-RETAINING SPECULUM.

By NATHAN BOZEMAN, M.D.,

NEW YORK.

The vagina, as a membranous canal, may properly be said to represent a truncated cone with the base turned upward and the apex downward, corresponding with its mouth.

The general outline of the organ, as viewed in its natural condition, is such as would result from bringing the two opposing walls of the cone together, the cervix uteri being encircled by it at the centre of its base, and its mouth closed by the falling together of the labia majora.

The line, therefore, formed by the anterior and posterior walls of the organ coming together is transverse, while that formed by the opposing surfaces of the labia is antero-posterior, being at right angles.

Now the most natural indications for the dilatation of this canal with the peculiarities named would appear to be, first, separation of the labia, and, second, the two opposing walls of the collapsed cone, so to speak. This, scarcely need I say, is the view generally taken of the relationship of these parts, and the usual practice is based upon it of bringing within the field of observation the cervix uteri and the two vaginal walls.

This plan of antero-posterior dilatation of the vagina, it matters not what form of speculum is used, I conceive to be a popular error, and it is wholly at variance with the true anatomical relationship of the parts. I shall presently attempt to explain more fully my meaning in our description of *a new form of speculum*, which I have the pleasure of presenting now to the notice of the profession. The principle of construction, as well as principle of action of this new instrument, will be found to differ from all others heretofore in use in several respects, which I shall explain farther on. Suffice it to say, one of the very essential differences is in what might be termed the working point of the instrument, that portion which is applied to the resistance. The blades of our instrument are introduced between the opposing walls of the vagina edgewise, instead of flatwise as formerly; and the dilatation is effected transversely or horizontally, as will be better understood when we come to explain the principle of action. The same instrument applies to the dilatation of the vulva as well as the vaginal canal; thus giving us at one glance a view of the parts from the mons veneris to the cervix uteri in front, and behind, nearly the whole of the posterior wall of the vagina—any and every point within this extensive range being accessible for operative purposes.

The dilatation thus effected is so regulated that the labia and the two extremities of the vagina are put upon the stretch only to the extent desired, which is in strict accordance with the anatomical conformation of the parts, this being of such a nature as to make the instrument *self-sustaining*, one of its peculiarities; another being *elasticity of flexure*. This principle of elasticity has never before been embodied in any form of speculum that I am aware of, and its utility and importance, in my judgment, cannot be too highly estimated. Instead of the hard, inflexible blade formerly used, touching only at one or two points soft and delicate structures, we have now the soft, elastic spring adapting itself to all the points of resistance with a uniformity to be attained in no other way.

The indications for complete dilatation of the vagina and vulva I conceive to be four:

1st. Elevation of the perinæum.

2d. Elevation and support of the upper part of the posterior wall of the vagina.

3d. Transverse dilatation of the labia majora and the mouth of the vagina.

4th. Distension and steadiness of the upper part of the anterior wall of the vagina, the vesico-vaginal septum.

Now these are the indications to be fulfilled, according to my judgment, independent of any and all efforts of the patient to the contrary; and any instrument, whether *self-retaining* or *not*, that does not meet these ends, must be regarded as incomplete. With my instrument I claim the accomplishment of all, *the fulfilment of the third and fourth indications* being an advance beyond all other methods, to say nothing of the *self-retaining* quality of the instrument, which it must be admitted is based upon more correct principles than any plan heretofore presented to the notice of the profession.

As regards the position of the patient I propose a few remarks before entering upon the description of our instrument, as I consider this of no little consequence in certain operations, especially those upon the anterior wall of the vagina.

While our speculum is equally well adapted to all positions, I prefer in the description and application of it to consider the patient resting upon her knees and breast, the body forming a right angle with the thighs, and the thighs a right angle with the legs. This position I now prefer to all others, and with propriety it may be termed the *right-angle position upon the knees.*

In no other position, according to my judgment, whether chloroform be used or not, can the patient be made so easy, comfortable, and secure, and without the aid of assistants. When folded up it is compact, light, and portable, and weighs only eleven pounds. It exceeds twelve inches in height, only on one side, the depth and width being twelve by eighteen inches. I hope before long to be able to publish a description of this *thoracic rest* or *support.*

We have come now to the most difficult part of our task, a description of this speculum.

Fig. 1 (half size) represents a front quarter view of the instrument, expanded as when introduced for use.

The general features of it as shown, are outstretched arms, expanded wings, rolling surfaces, standing and projecting arches, broad, contracted, narrow and rounded points; and the thumb-screw arrangement indicates that the whole is moved by a system of leverage.

The proportions of the instrument are, I think, in harmony, and the construction will be found to be in strict accordance with well-known geometrical principles. It may be said to be composed of two simple, similar bent steel levers, about 8¼ inches in length, rounded and flattened at certain points, having elasticity of flexure, and connected at one extremity by a pivot joint G, around which they revolve horizontally.

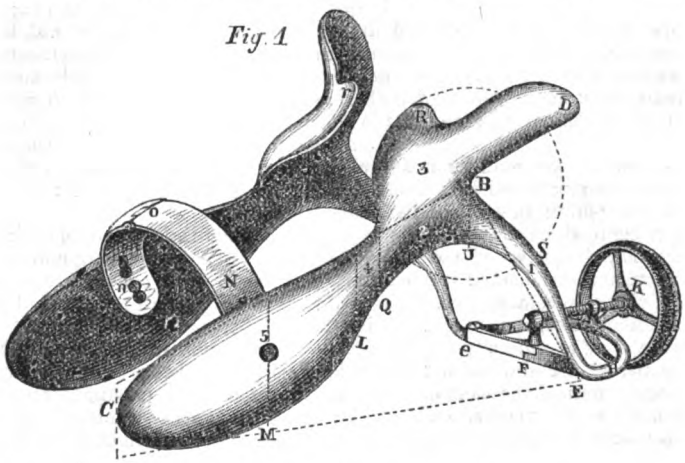
For description, therefore, as is most naturally suggested from its general outline, it may properly be divided into the foot and heel, including thumb-screw and short levers, and into the legs, body, wings, neck, and arms or blades, as indicated by Figs. 1, 2, 3, 4, and 5.

The description of the foot and heel we will defer until we come to study the principle of action.

I shall consider B the centre of the instrument; the plumb line U, dropped from it, the balancing-point.

The legs where they leave the heel E and *e* are r unded, a quarter of an inch in thickness, and for a short distance ascend almost perpendicularly, inclining slightly forward and inward. In the next part of their course they become gradually more and more flattened, extending now almost directly forward, only inclining slightly outward.

The line U indicates their union with the body. Their length is two inches and three-eighths. This part of the instrument applies to the purpose of dilating the vulva or labia majora. The lower part of the legs falls just within the fold formed by the inner part of the thigh and the labia, while the upper portion passes between the latter about the commencement of the nymphæ, and



thus reaches the mouth of the vagina, which corresponds exactly with the plumb line U, the balancing-point.

The body is included between the two lines U and Q, and is somewhat quadrangular in shape, rounding on its outer surface and hollowed out on the inner side to the same extent as the upper part of the leg and the wing standing upon its upper edge, as indicated by the line B Q. This part of the instrument is applied directly to the transverse dilatation of the mouth of the vagina. The wing is of a peculiar shape, and for the sake of description may be divided into the lower and inner portion and the upper and outer portion. The first part presents a rounded surface from right to left, and up toward the projecting angles R *r* looks almost directly forward. These projecting arches are about three-quarters of an inch wide, and at the angles are about three-quarters of an inch above a line drawn across from centre to centre. This part of the wing, with its fellow of the opposite side, gives support to the perinæum, which lies across from one to the other, just as the bridge spans the stream. The upper and outer portion of the wing looks forward and outward, and is intended to support the buttock. The neck between the two plumb lines Q, L, is about half an inch in length and width, and as shown is the most contracted part of the arms. This point comes just within the mouth of the vagina, and consequently prevents painful stretching of the parts here in the expansion of the blades.

The arms or blades form the widest part of the instrument, and are intended to distend and steady the vesico-vaginal septum. They are thin, spoon-shaped, about two inches and three-eighths in length, and at M one and a half inches wide. On the middle of this line is seen the countersunk head of the rivet which passes through here and gives support on the inside to the extremities of the arch N *n*, connecting the blades at this point. This arch is four and a half inches in length, connected in its middle by a hinge joint O, and about three-quarters of an inch in width. It should be made of steel, and so thin between the joint and extremities as to allow of easy bending in the opening and shutting of the arms. There are two holes near each end, with slits in upper edge to encircle the narrow neck of the rivet when in use. This arch may be used or not, as circumstances may require, it being easily slipped off or on. When used it is intended to elevate and support the upper part of the posterior wall of the vagina, it being the fulfilment of our second indication. It is easily elevated or depressed with the finger, and when in position stands about one inch above the edges of the blades, and on a plane slightly above that of the projecting angles of the wings R *r*. Nearly the whole of the instrument, as will be seen by reference to the figure, is included within the legs of the right-angled triangle E B C, only the foot, legs, and wings being outside. The circle D R Q S has its centre at B, the centre of the instrument, with a radius of one inch and a quarter, the length of the line of union between the root of the wing and the body. This circle, as is seen, includes nearly the whole of the wing, the body, and a large part of the leg. This angle and centre of circle, I should observe, are important points to be borne in mind in the manufacture of the instrument. They should be preserved in all cases, it matters not what change may be found necessary as regards proportions.

The instrument, when set upon a table, has its foot flat upon the surface, touching nowhere else excepting at the point near the ends of the blades, as indicated by the base line of the angle E C, which measures four inches and three-quarters. The leg E B measures two inches and three-quarters, and C B four inches and a half.

From centre B to corresponding point of opposite side, the distance is two inches and a quarter. Between tips of wings D *d*, four inches and a quarter. Between commencement of neck Q, three inches. Between blades at M, measuring from outside to outside, four inches. Between points measured in the same way, three inches and a half.

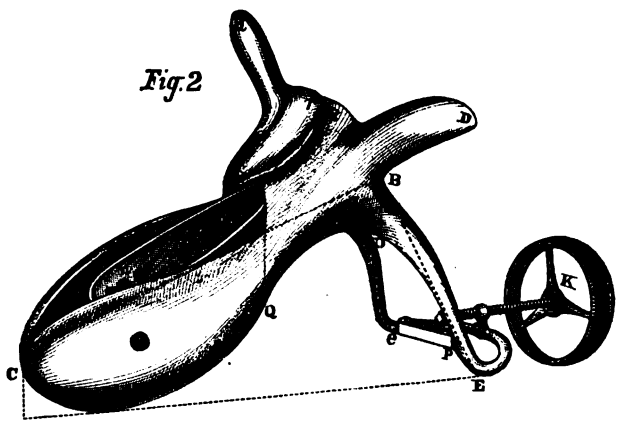
The instrument is to be made of steel, electro-plated, as light as is consistent with the strength required, there being certain points, of course, where this is an important feature; for example, the foot and heel of the instrument.

The *elasticity* of *flexure*, it should be borne in mind,

extends only from the heel to the extremities of the blades, increasing of course in extent as the latter points are approached. The limit of elasticity at the points of the blades should not exceed three-quarters of an inch under any amount of resistance here, and this should be borne in mind in *tempering* the instrument, otherwise the limit might be exceeded, and the usefulness of the instrument thereby endangered.

Fig 2 represents the instrument closed, ready for introduction or withdrawal. It being collapsed, so to

Fig. 2



speak, every point of the opposing sides is brought into closer relationship. The elevated arch standing above the edges of the arms or blades, as seen in the first view, is now folded within them, the upper part of it resting beneath the hugging arches, R r.

In this view of the instrument, there are three divisions made by the two plumb lines U and Q, which are important as directing attention to the uses of the respective portions. The leg, for example, included within the first division, performs the part of separating the *labia majora*. The wings and body of the second division elevate the *perinæum*, and open the *mouth of the vagina*, to the utmost limit transversely. The arms or blades of the third division *unfold* and *steady* the *vesico-vaginal septum*, or upper part of the anterior wall of the vagina, and at the same time give support to the two extremities of the arch which spans the space between them, and receives upon its top the *falling posterior wall of the vagina*.

The thumb-screw K is seen reversed to its fullest extent, and the two short levers quietly folded within the foot of the instrument, the point P being now in close proximity to the pivot G.

We come now to a consideration of the principle of the instrument, and I will state in the outset, as thus applied it is new and original with myself, it never having been applied before, that I am aware of, by any one, to the purposes of a speculum.

The principle itself, however, is an old one, as regards its application to other purposes. It will be familiar to those who may have seen a certain kind of *cotton press* in the Southern States, in which it is employed, though with a more extensive system of leverage than I have here. I got the idea myself from seeing the above application; and the credit I am entitled to is the modification which I have made of it, to suit the purposes of a *self-retaining* speculum, the principle of which we will now attempt to describe. This principle, as here applied, I have no hesitancy in saying, forms one of the most beautiful illustrations of the parallelogram of forces as producing curvilinear motion that could be conceived, and answers, in the most satisfactory manner, the purpose for which it is here intended.

In studying the law of forces, there are several important points always to be borne in mind, whether applied to the rudest lever or pulley, or to the most complex piece of machinery. As these points are or are not understood, depends success or failure.

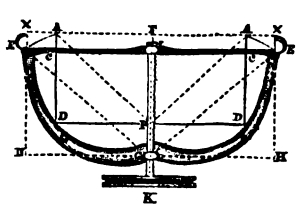
Professor Silliman,* who is authority in matters of this sort, says: "To determine a force with precision, we must consider three things: 1st. The point of application. 2d. The direction. 3d. The intensity or energy with which the force acts."

Inattention to one or more of these rules has, I am satisfied, caused the failure of all previous efforts at getting up a *self-retaining speculum*, to fulfil all the indications previously named. I am free to confess myself that I failed in many of my efforts from this very cause.

My greatest error I now conceive to have been in the point selected for the application of force. Had I the time and space, it might be interesting to show how I labored to extricate myself from this difficulty; but as it is, I shall be content for the present with saying that this instrument, as here exhibited, is not the work of a day, or a week, or a month, but years of patient thought and repeated disappointments.

Let us now turn our attention to the diagram, Fig. 3, which is also a half-size front view of what I have

Fig. 3.



denominated the foot of the instrument, here represented closed and expanded, with both legs cut off at the heel E and E.

The two sides E h G together form, as is seen, almost a semi-circle, with a radius of one and a quarter inches. In the middle, where they unite, is the pivot-joint G, and here is the point of our application of force.

These arms are inflexible, somewhat round, and almost of uniform thickness, not exceeding a quarter of an inch

* Principles of Physics.

anywhere, excepting at the pivot and ends, where they swell out a little, to give additional strength.

Within these arms is situated our plan of leverage for opening and shutting the instrument. This consists of a double-threaded thumb-screw K, about one inch and three-quarters in length, and three-eighths of an inch in thickness, with an open wheel on the outer end, one inch and an eighth in diameter; and of two short, stout levers, one and a quarter inches long. These latter are connected at one extremity by a joint at the heel E and E, two and a half inches from the pivot G. At the other extremity they are connected together by a joint at P. Rising above, three-eighths of an inch, is to be seen the connecting screw of this joint, expanded, and perforated to receive the extremity of the thumb-screw, upon the extremity of which, on the outside, is placed a small tap. In the same manner the thumb-screw passes through the connecting pivot-screw G, which is the nut, the former being free to move both forward and backward.

Let the two lines now on each side, A D and P D, represent the instrument closed, A *f* and P *f* completing the rectangle or square. (An error in the cut; it should be a small *f*.) The diagonal P A will then represent the situation and relationship of the two short levers previously described.

To open or expand these arms now to the full extent, we have, as would appear, two forces, A P and A P, acting at an oblique angle, a very great mechanical disadvantage, as will be readily understood, for "when a force acts upon a body at any other than a right angle, a part of its effect is lost."

The difficulty, however, is overcome and the accomplishment of our purpose rendered easy by resolving each of these oblique forces into two, P *f* and A *f*, one parallel and the other perpendicular to the point to be moved. This is effected by revolving the thumb-screw K until it assumes the position of G F, and the short levers that of E F and E F. The latter together now form a straight line—a relationship that places the whole instrument in a state of equilibrium; the weight of the two sides, being equal, is exactly counterpoised at F. Complete now the parallelogram E H G, and we have the diagonal G E, the resultant of the two components thus applied, which give us the diagonal or oblique relationship of the arms of the instrument which is here so beautifully carried out. In this resolution of forces, therefore, our power is seen to pass through the arc of a circle which is the diagonal of the small parallelogram A *c*, E *x*, the distance A E being three-eighths of an inch. As it is with the seat of power so it is with every other part of the instrument to the extremity of its blades, which, with varying radii, pass through the arc of a circle the length as well as the velocity of which increases with the distance from the pivot G.

For instance, at the centre or balancing-point of the instrument U, Fig. 1, corresponding to the mouth of the vagina and about one inch from the seat of power, we have the arc increased from three-eighths to half an inch, with a total expansion of the arms at this point of two and a half inches. And at the extremity of the blades, a distance of about five inches from the same point, the arc is increased to one and a half inches, giving us a space between the opposing blades of three inches for operative purposes.

At the two points named the limit of expansion of the blades corresponds exactly with the limit of the dilatation of the mouth of the vagina, and its upper extremity, which alone is sufficient to explain the *self-sustaining* and *self-retaining* feature of the instrument.

In the application of our power then to the thumb-screw K, the position of it is most advantageous for producing its maximum effect in collapsing or carrying the two short levers from their oblique relationship to that of right angles with the point acted upon, thus affording an example of increased power with increased resistance. The instrument with the above system of leverage may properly be said to represent a *double bent lever*, the most familiar example of which is the *fire-tongs*. Unlike these, however, it has the power applied on the inside instead of the outside. Alike, though, in the important respect of having the power applied between the fulcrum and the weight or resistance, distinguishing both at once as levers of the third class.

This instrument I shall call *a spring and self-retaining speculum*, as is most naturally suggested from these two distinguishing qualities of it.

I think I may justly claim for this speculum originality in:

1st. The system of leverage employed, possessing as it does regulated and increased power, reduced to the smallest possible compass, and far away from the mouth of the vagina, thus allowing the freest and widest range of manipulation with instruments, compatible with the nature of these parts.

2d. Transverse action of the instrument, with uniformly varying movement of the working-point, extending from the heel to the point of the blades, thus making the lateral walls of the vagina the seat of pressure instead of the anterior and posterior, as formerly.

3d. Complete exposure, at the same time, for operative purposes of the vulva, both walls of the vagina, and the cervix uteri, with the two polished surfaces of the arms of the instrument standing upon the sides, the most favorable position in which they could be placed to secure the greatest amount of reflected light.

4th. Elasticity of the working-point of the instrument.

5th. Being self-retaining in the fullest sense of the word.

6th. Being equally applicable in its use to all positions of the patient.

7th. Allowing all operations to be done without the aid of assistants, or exposure of the person of the patient, further than the parts immediately brought within the field of observation by the expansion of the arms of the instrument.

All of these points, I am safe in saying, admit of the clearest demonstration.

Remarks.—Having now completed the description of our *spring and self-retaining speculum*, it remains for us to offer a few additional remarks upon its application in practice, and the circumstances under which it was first done; for it is reasonable to conclude that the question will be asked, where is the proof of all the advantages which have been portrayed at such length?

The only proof I propose to offer, and I think this conclusive, is the application of the instrument in a single case, the very one to which it was adapted in completing it as here shown. This case being an extreme one, as will appear, has the advantage, I think, of rendering the proof convincing to the practical mind, and lessens the necessity, I conceive, of additional corroborative testimony to satisfy even the most skeptical. The case referred to was one of vesico-vaginal fistule occurring in a very stout, fleshy woman, weighing upwards of two hundred pounds. Early in October last she was admitted into that admirably conducted institution under the direction of the Sisters of the Hoboken St. Mary's Hospital, where my patients are now received.

The fistule was of six or eight months' standing; small, not larger than a pin's head, and occupied what we would ordinarily term a favorable position, being some three inches above the *meatus urinarius*, and near the edge of the septum, upon the left side.

The peculiarity and difficulties of the case were these: Anteversion of the uterus; a convoluted or folded condition of the two opposing walls of the vagina, which was of immense size; and a pleated condition of the edges of the fistule, and the parts immediately surrounding it.

Assisted by Drs. Finnell, Connolly, Lynch, Metcalfe, and several other medical gentlemen of New York, and Dr. Chobert, of Hoboken, I undertook my usual operation, the patient resting upon her knees and elbows. My fourth size of the lever speculum, with a blade four inches long, one and a half inches wide at the heel, and one and three-quarter inches near the point, was employed; and although of such large size, this instrument, with spatulas and depressors, brought to bear from various points by assistants, afforded us only an imperfect view of the very small fistule. The upper part of the posterior wall of the vagina came down in such immense folds over the end of the instrument, met by the same folded and protruded condition of the anterior wall, under violent and almost continuous expulsive efforts, that it became quite impossible to commence the process of paring the edges of the fistule, and to complete it in a regular manner. This stage of the operation, however, was gone through with after the length of time indicated, only to be followed by a still greater difficulty and delay in the next—the introduction of our sutures—only three being called for. The patient, at this stage of the operation, was placed upon her side and chloroformed, which, however, afforded us no relief from the surrounding difficulties.

Suffice it to say, the operation, after three hours, with five or six assistants, was finished, though in the most unsatisfactory manner it had ever been my misfortune to encounter before.

Now, after all our labor and annoyance, I felt that a failure was inevitable, and so expressed myself to the gentlemen present. The removal of our suture apparatus on the eighth day proved too truly the correctness of our misgivings as to the final result. There was a total failure.

With a full understanding now of the difficulties of the case, and seeing the result of the extraordinary efforts which had been made in this operation, I contemplated, I frankly confess, another operation with dread and ill forebodings.

I determined, however, that I would not undertake another until I could devise some plan of securing the patient effectually in the right-angle position upon the knees, which I had had in contemplation for several years; and, if possible, to complete my new speculum, believing that no better case could be found to test its merits. Accordingly, I drew a plan of my *thoracic rest*, alluded to in the former part of this paper, and placed it in the hands of a carpenter, who had it ready for use in five or six days.

As to the speculum, this was not so easily completed, as it involved a radical change in my original plan, arising from a fundamental error in its construction, which I had not discovered until this particular juncture. An explanation of this change would necessarily require a description of the instrument and all the alterations made in it from the beginning, which would far exceed the limits assigned to these remarks in the outset.

On the 20th of November it was so near completed as to enable us to use it.

The patient was now placed in our new position, and thus secured upon the *thoracic rest*. The position was now found to be admirable, and the confinement of the patient perfect.

Chloroform was next administered, and our speculum, as here shown and described, was introduced and expanded to the fullest extent. A reference to the limit pointed out on a former page will give some idea of the enormous size of the vagina. In short, the dilatation of the vagina, regarding all the indications which we have pointed out, was most complete and satisfactory. The insignificant fistule which we had labored so hard to bring into view a few weeks before and failed, now showed itself in its fullest dimensions, steady and immovable, even in the very face of the most violent expulsive efforts of the patient from bearing down and vomiting, before which we stood almost powerless and helpless in the previous operation, with every assistant that could be employed.

I now viewed the parts of operative procedure for the first time with a feeling of certainty as to the result. At my leisure I began the operation, and quietly completed it by my ordinary method, without the aid of an assistant, further than to wash sponges and give chloroform.

In twenty-five minutes our patient was removed from the table and placed in bed, totally unconscious of what had been done. Ten minutes of this time, I should observe, were lost in consequence of a little hæmorrhage which had to be controlled before introducing our sutures.

Thus was achieved, I conceive, the greatest triumph of our professional life.

The above operation was done in the presence of Drs. Thomas C. Finnell, Thomas S. Bahan, Joseph S. Crane, of New York, and Dr. Chobert, of Hoboken, all of whom expressed their entire satisfaction at the result.

To Dr. Finnell I am under many obligations for having so opportunely placed under my charge the above patient, so well adapted to the completion of our instrument. Without such an opportunity our success might have been deferred many months longer. There are also due Dr. Chobert many thanks for his kind attention to the patient during the after treatment.

The result in this case, however satisfactory it may be viewed in the important respects mentioned, merits additional interest, I think, from the fact that the instrument actually employed in the case, and from which these drawings have been made, was completed by my own hands in *gutta percha, sheet lead, and iron wire.* To Messrs. Geo. Tiemann & Co., 67 Chatham street, however, I am under great obligations as regards the foot, leverage, and legs of the instrument, and the many changes and alterations made from time to time in order to reach this stage of completion. They placed at my disposal an experienced and finished workman, who made and put together almost every part of the instrument above named under my own supervision. Without this very great advantage I never could have gone through with the work even to this extent.

As regards the ultimate success of this instrument, from what we have seen thus far in its application I think I can very confidently recommend it to the general practitioner as well as the surgeon, as likely to give satisfaction in all cases where a speculum requires to be used.

That a diminution of the size of the instrument shown here will have to be made to suit the majority of cases I am convinced. This is an extra large size. A medium size, I think, will cover four-fifths of all cases; one smaller size, and a larger one, such as here shown,

covering the other fifth of the cases. In this last class we include such cases as the one above detailed, and all cases with shortening of the vagina resulting from injury of its walls or otherwise. As soon as we can determine properly the alterations necessary to be made in the proportions of this instrument, in order to reach the other two sizes, we will have them made.

The instrument, when completed in steel and electroplated, as designed, will not, I am satisfied, exceed the weight of this our original pattern, which is only eight ounces, being two ounces less than the ordinary lever speculum.

FIFTH AVENUE HOTEL.

CASE OF
ANÆMIA AND DYSMENORRHŒA TREATED BY GENERAL ELECTRIZATION.

BY GEO. M. BEARD, M.D.,

LECTURER ON NERVOUS DISEASES IN THE UNIVERSITY OF NEW YORK,

AND

A. D. ROCKWELL, M.D.,

OF NEW YORK.

IN our recent papers before the Academy of Medicine and the Medical Society of the County of New York, we stated the principle on which we employ general electrization in certain uterine symptoms, and also detailed a number of cases illustrative of the powerful constitutional tonic effects of this method of treatment in amenorrhœa, dysmenorrhœa, menorrhagia, etc., associated with general debility, and not dependent on incurable organic disease.

The great mistake that we are all liable to make in our study of the therapeutical uses of electrization is the confounding of *symptoms* with *diseases*.

In regard to the indications for general electrization, the question to be asked is not whether it be good for this or for that affection, but whether in any case of disease (no matter what its name may be) *we desire a powerful constitutional tonic impression.*

Whether the tonic influence that is received from general electrization succeed in curing or relieving the special symptoms, associated with the general debility, will depend on the constitution of the patient, and on the thoroughness and persistence of the treatment.

In all the painful affections of the female genital system, where electrization is indicated, temporary relief is usually afforded by an application of but a few moments in duration; but permanent cure or dissipation of the symptoms is only achieved by thorough and persistent treatment, studiously varied and adapted to each individual case.

We have sometimes succeeded by general electrization where internal tonics and localized electrization have failed. It is needless to say that we sometimes meet with obstinate and obscure cases of uterine disorder that are as rebellious to general electrization as to all other systems of treatment.

We have thus far met with the best and most uniform success in the treatment of dysmenorrhœa, especially of the neuralgic variety, and in chlorosis.

With amenorrhœa the results are as various as are the causes that produce it.

In mere temporary suppression, the menses are sometimes brought on by one or two applications; but in long-standing amenorrhœa we can hope for abiding results only from a persevering course of treatment continued for several weeks.

According to our experience the tonic effects of general electrization are as permanent as those which are obtained from the use of iron, bark, strychnine, cold bathing, and other tonic influences that we are all accustomed to prescribe.

The following case, which has not before been published, is typical of a number in which we have obtained similar or approximative results.

CASE.—Miss D., aged 21, came to this city from Auburn, to be treated for the variety of dysmenorrhœa termed neuralgic. The treatment by ordinary internal medication was continued some two months, but as the neuralgic pain seemed to be but little relieved, and as her general condition did not improve, she was induced to try the effects of general electrization, before returning to her home. She commenced to menstruate at irregular intervals when about fifteen years of age, and from the first had suffered more or less at each menstrual period. Her general health began to fail some three years before she visited this city for treatment, and when she came under our observation she presented the following symptoms:

She was decidedly anæmic, and the general appearance of lassitude and discouragement which she presented at once betrayed the disturbance of her vital forces. While in many instances of neuralgic dysmenorrhœa the pain seems to be confined solely to those nerves that supply the sexual organs, in this case the disorder extended to the whole system. The constant recurrence and terrible paroxysms of pain from which she suffered rendered life a burden. Even in the intervening time, anticipation of the agony that she again must so soon undergo, caused her to suffer from great depression and melancholy.

In addition to these distressing pains she suffered from profuse menorrhagia, so that what little strength she regained after her sickness, was almost immediately lost on the return of the catamenia. Her bowels had been for a long time obstinately constipated, and unless this state were frequently relieved by aperients she was annoyed by considerable vertigo and headache. She began to despair of ever obtaining relief. She received the first application of general electrization in November, 1866. A very mild and fine current was used, and the application was extended from the neck, down the spine, and over the vital organs.

Although she was submitted to the influence of the current for but five minutes, yet during the application she showed symptoms of faintness, and on the following day she suffered from considerable soreness and nervous prostration. She visited us on three different occasions when her courses appeared, and were as long continued and attended with as great loss of blood as before. There was, however, considerable amelioration of pain. Before the cessation of the flow, we renewed the operations, and continued the treatment uninterruptedly for nearly four weeks. She received an application every other day, and was soon able to bear a current of ordinary intensity. The improvement in her general condition was exceedingly rapid. The capricious appetite became less exacting and the constipated bowels more regular. After a very few applications had been given and the tonic influence of electrization began to manifest itself, she appeared a different person both as to mind and body. When her menses again appeared she suffered but little more pain than is usual, and the general neuralgic distress was quite wanting.

The menorrhagia, which before was such a prominent and debilitating symptom, was now so slight as scarcely to deserve the name. She received subsequently three more applications, when she returned to her home. We were of course anxious to know if this favorable state of things continued, and have been

gratified to learn by direct information that since she discontinued treatment there has been no return of any prominent distressing symptom. She has, moreover, continued to improve in her general condition, until she is now in quite robust health.

914 Broadway.

Original Lectures.

LECTURES ON TUMORS:

BEING PORTION OF THE COURSE ON SURGERY AT THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

Session 1867-8.

By S. D. GROSS, M.D., LL.D.,

PROFESSOR OF SURGERY.

(Reported expressly for the Medical Record.)

I.

This is a subject of great importance, for there is no community in which tumors do not constantly present themselves in some form or other, or in some part of the body or other. It is well therefore that the physician should have a general knowledge at all events of this class of formations. They are liable to occur in all organs and tissues of the body, almost without exception, just precisely as wounds, just precisely as inflammation.

A tumor may be defined to be an enlargement of a part, of a tissue, or of an organ, the result of abnormal deposit. This abnormal deposit may be a superaddition, it may be a new product, or it may be precisely similar to that which is naturally going on under all circumstances of health in the tissues, organs, or structures of the human body. Some of these formations are *benign;* others are *malignant.* The benign tumors may be of new formation, the result of new deposit, or simply the result of inflammatory irritation, or super-nutrition—hyper-nutrition, if you please so to consider it.

The malignant formations are, so far as we are acquainted with them, always the results of deposits of new character; they are additions to the preëxisting tissues.

The number of malignant formations is comparatively small; we have, in the first place, *scirrhus;* secondly, *encephaloid;* thirdly, *melanosis;* fourthly, *colloid;* and lastly, *epithelioma;*—five malignant, heterologous or cancerous formations; those which destroy the part in which they occur, and ultimately, if they are allowed to pursue their course, also the life of the individual; they are therefore called *malignant.*

The *benign,* innocuous, or harmless formations—those which do not assume a malignant character—are much more numerous, twice, if not more than twice, as numerous as the malignant; and a great many of them are simply the result of hypertrophy, or a supernutrition, or the addition of a material which is naturally deposited in the tissues, organs, or structures of the body.

There are few situations in which tumors, benign or malignant, may not arise; if there is any exception at all, it is the aponeuroses, the fibrous structures as they are called, and the tendons, the ligaments, and the blood-vessels; but it is questionable whether even these are not occasionally the seat of both of these formations.

Tumors are liable to occur in the external portions of the body as well as in the internal organs.

The *consistence* of a tumor varies according to its nature, according to the character of the affected organ, according to its age, and other circumstances. Thus, a tumor may, in the first instance, be fluid; by and by it may become more or less solid; ultimately perhaps entirely solid: or, instead of this, the tumor may be fluid from its commencement, and continue in this condition during the remainder of its existence, no matter how protracted this may be: or a tumor may be partly fluid and partly solid, and this may be in different portions of its extent, and another part may be semi-fluid, or semi-solid, depending upon circumstances. In the earlier stages of their existence, tumors, as a general principle, are softer than in their advanced stages, because as the period of their duration continues they acquire a greater degree of solidity.

Tumors vary very much in their *volume;* thus there may be a tumor not larger than a millet seed, or a small pea, or a cherry; and, on the other hand, it may be as large almost as the body upon which it grows. The late Dr. Francis, of New York, reported many years ago a case of fibrous tumor of the uterus which weighed one hundred and four or five pounds. Elephantiasis of the scrotum sometimes acquires an enormous bulk; cases are on record of tumors of this kind weighing upward of one hundred and fifty pounds. I have myself repeatedly drawn off water from ovarian cysts amounting to upward of ten gallons, in one instance twelve gallons; and still larger quantities have been drawn off from a cyst of this kind. These remarks will give you an idea of the size a tumor may acquire.

The *form* of a tumor varies in different cases; in some it is perfectly round, in others conical, in others pyriform, in others exceedingly irregular, and in many instances we find that it is nodulated, or marked by elevations and depressions.

The shape of the tumor is very much influenced by the structure in which it occurs, much more than by its nature; if there is much pressure exerted on the tumor, its tendency will be to flattening, in consequence of the resistance afforded by the tissues among or in which it is situated. If there is no compression exerted upon the tumor it may grow to any bulk and acquire any configuration or conformation.

They may be *simple* or *multilocular,* that is, they may consist of single cysts or of several cysts; large tumors are often composed of series of similar masses united together by fibrous or fibrous and cellular tissue.

The *color* of a tumor varies according to circumstances, a matter of comparatively little consequence in the consideration of the history of such a growth. It is only when a tumor is external, or grows in any of the mucous outlets of the body, as the nose, throat, anus, vagina, or lower extremity of the uterus, that we can observe the color, and in that way deduce important conclusions in reference to the nature of the affection. Thus when I look into a person's nose, and find that it is filled with a tumor having a whitish, greenish, or gelatinous appearance, much like that of an ordinary oyster, I make up my mind at once that I have to deal with a tumor which is benign, innocuous, or harmless in its character; if, on the other hand, the tumor is very vascular, red, or of a bluish or livid aspect, then I make up my mind that it is of a very different character, that it is fibroid; and if it is very vascular, scarlet in its complexion, liable to bleed, and growing very rapidly, then I make up my mind that I have to deal with an encephaloid tumor, or a tumor of a malignant character. So in regard to these growths as they occur in the vagina or the uterus. Color, therefore, is of importance when the tumor is exposed to view.

The *mobility* of a tumor varies in different cases. Some tumors are movable during the whole period of their existence, from their commencement to their termination, as, for example, when they are situated superficially. Thus a sebaceous tumor of the scalp can be readily moved about in different directions; so in regard to some other tumors, as the fatty, especially when pendulous. But there are other tumors which

have firm adhesions and are immovable, and cannot be pushed about from one point to another; and this is the case frequently from their very commencement, and they so continue during the whole of their connection with the parts in which they are developed. As a general rule, it is a good sign when there is a certain degree of mobility in a tumor. A tumor connected with a bone is generally immovably fixed. A malignant tumor, at a comparatively early period of its growth, *forms adhesions* in the surrounding structures, as is seen in cancer of the mammary gland. Here, during the progress of the affection, lymph is poured out between the affected gland and the surrounding structures, by which the parts become firmly united together, so that when we perform an operation for its extirpation, we are obliged to use the knife extensively in order to effect the detachment. So also in tumors of benign character when they are developed among the muscles, or when they are situated comparatively superficially; the pressure on the surrounding parts excites inflammation, lymph is poured out, and strong adhesions are formed. Again, a part may be bound down merely by the tension of the muscles, aponeuroses, tendons, and other structures, without any aid whatever from plasma, lymph, or fibrin.

The *sensibility* of tumors varies according to circumstances. The benign growth is rarely attended with any sensibility unless it compresses an important nerve. Then there may be pain, which may be stationary or constant; there may be numbness in the parts around and beyond the seat of the tumor, owing to compression of the nerves and the imperfect transmission of the nerve-fluid. Generally such tumors are free from pain, or if there be pain, it is comparatively slight; whereas in malignant tumors, especially in scirrhus, there is usually pain at a very early stage, and pain which goes on gradually increasing in severity until at length it becomes distressing, depriving the patient of appetite and sleep, and requiring anodynes for its relief.

The relations which tumors bear to the surrounding structures are worthy of consideration. Every tumor must have a habitation, a residence. It is developed at a particular point, and, as it increases in size, it gradually encroaches on the surrounding structures, until at length it has not room enough for its development, and then must produce more or less serious effects upon the adjacent parts as well as on the system at large. In consequence of this pressure, as well as the short life of some of these tumors, we find that there is a tendency to ulceration and to elimination.

The benign tumors generally retain their vitality unimpaired for a considerable length of time, frequently for many years. In many cases, especially in the malignant formations, ulceration takes place at a comparatively early period, in consequence of the pressure on the tumor exercised by the superjacent structures, and in consequence also of its peculiar organization; and in this way an open sore is formed, peculiar in its character, attended with a peculiar discharge, attended with a peculiar pain.

Occasionally there is important involvement of the lymphatic ganglions around. This is the case sometimes in the benign tumors, but comparatively seldom; whereas in the malignant formations, as scirrhus, melanosis, etc., the lymphatic ganglions usually become affected in a comparatively short time. The nearest lymphatic ganglions always suffer in this way; thus, in cancer of the penis, the lymphatic ganglions of the groin become involved; in cancer of the lip, those of the jaw and the chin; in cancer of the mammary gland, the lymphatic ganglions of the axilla are invaded; all this as a necessary result, as it were, of a contaminated condition of these structures from the preëxisting disease in the neighboring organ, tissue, or structure.

As already mentioned, I make two great distinctions of tumors or morbid growths: the *benign* and the *malignant;* the malignant are also known under the name of the heterologous, heteroclite, or heteromorphous formations.

BENIGN TUMORS.

Commencing with the more simple benign, innocuous, or harmless tumors, we have;—

In the first place, the *hypertrophic* tumor, the result of hypertrophy or supernutrition, a sort of outgrowth of the natural tissue, structure, or organ, where the formation occurs;—

In the second place, there is what may be called the *vascular* tumor, composed essentially of vessels in a state of enlargement and morbid alteration;—

In the third place, there is the *adipose* or *fatty* tumor, nothing but a hypertrophic condition of the natural adipose or fatty tissue, the tissue which occurs in such great abundance in certain individuals in different parts of the body;—

In the fourth place, we have what is called the *horny* tumor, or the corneous tumor, a tumor resembling the horn of some of the inferior animals, as, for example, the goat;—

In the fifth place, we have the *fibroid* tumor, or the fibrous tumor as it is not unfrequently called, a tumor composed essentially of a substance r sembling some of the preëxisting normal or natural tissues, as, for example, the sclerotic coat of the eye, the dura mater, the pericardium, the proper coat of the testicle, the aponeuroses, periosteum, etc., composed essentially of fibrous tissue;—

In the sixth place, we have the *cartilaginous* tumor, so called from the resemblance which it bears to the cartilaginous tissue, composed of a gristly texture, firmer than the fibroid tumor, less firm than the bony tumor—the enchondromatous tumor as it is sometimes denominated;—

Then, in the seventh place, we have the *osseous* tumor, the bony tumor, a tumor resembling essentially the natural bony tissue, resembling it but not identical with it, as you observe in the various specimens on the table;—

Then we have, in the eighth place, the *calcareous* tumor, or earthy tumor, a tumor of exceedingly rare occurrence, most generally found in connection with a degenerated lymphatic ganglion of the neck, groin, or bronchial tubes; or in the uterus, in connection perhaps with the fibroid or fibro-cartilaginous tumor of that organ;—

We have, in the ninth place, the *neuromatous* tumor, a tumor developed along the course of a nerve, composed of an expansion of the nerve-fibre, with the addition of a large quantity of the fibrous or fibroid element, such as that which enters so largely into the composition of the ordinary fibroid development;—

Tenthly, we have the *cystic* tumor, which is exceedingly common, and which may be an original growth, or it may simply be an outgrowth of the preëxisting structure;—

Eleventhly, we have the *hydatic* tumor, a tumor composed essentially of hydatids, found most frequently in the liver and in the ovary;—

Twelfthly, we have the *polypoid* tumor, met with chiefly in the cavities of the nose, the uterus, vagina, larynx, fauces, ear, urethra, and the urinary bladder, in a word, in the mucous outlets of the body; called polypoid from its resemblance to a polyp;—

And in the last place, there is the *myeloid* tumor, orig-

inally described by Lebert and Paget, a tumor the existence of which is not yet fully determined; my conviction is, judging from the history of this development, and from what I have seen of it, that it is nothing but a form of encephaloid tumor, fungus hematodes, or soft cancer, and consequently a malignant formation. We have, therefore, including the myeloid tumor of Lebert and Paget, thirteen distinct growths of this kind.

NO. I.—HYPERTROPHIC TUMORS.

The hypertrophic tumor is simply an outgrowth of a preëxisting structure, tissue, or organ; it is simply, in other words, hypertrophy of a preëxisting part, the result of supernutrition, of overgrowth, of inordinate vascular activity, attended with deposit of plastic matter, and the organization of this matter, so that, at length, it becomes part and parcel of the tissue with which it is incorporated. I can give you a good idea of this form of tumor by referring you to what so frequently occurs in enlargement of the tonsils. In persons of scrofulous temperament or predisposition, these glands are exceedingly liable to become enlarged, expecially in young children under the age of nine or ten; the slightest exposure to cold will bring on an attack of this kind; and when the enlargement has progressed to some extent, then this being the weak part of the body, whenever the patient takes cold, or is laboring under disorder of the general health, however induced, there will be apt to be an increased activity in these structures, followed by augmentation of their size. Now these organs exist in the natural state, and we account for the enlargement by supposing that, in consequence of the irritation or inflammation which takes place from the causes mentioned, there is an increased flow of blood to them, that their vessels become enlarged in consequence and thus carry more blood than in the normal state, and these vessels, under the influence of this irritation or inflammation, or both, deposit plasma, lymph, or fibrin, in larger quantity than they do in the natural state simply for the purpose of nourishing or keeping up the growth or vitality of these bodies; the fibrin is intimately connected with the process of nutrition, which, under such circumstances, is simply in a state of perversion; there is simply an increase of it, hypertrophy—and hence we say that a tumor of this kind is a "hypertrophic" tumor. So in regard to what is called goitre, bronchocele, or the "Derbyshire neck." It is an enlargement of the thyroid gland, situated at the sides of the larynx and upper portions of the trachea, consisting of two lobes connected at the middle line by what is called the isthmus of the gland. What the precise function or structure of this body is, has not been determined; but we know that it is liable to the formation of a tumor, especially frequent in certain regions of the world, as the mountainous regions of the United States, of Switzerland, Italy, Germany, France, the Indies, China, &c., from what cause, we cannot determine.

We have another instance of this form of tumor, in old age, in enlargement of the prostate gland. Then we have elephantiasis of the scrotum, consisting of hypertrophy of the skin and subcutaneous cellular tissue. Cases of this kind are on record where the tumor weighed respectively one hundred and twenty, and one hundred and sixty or sixty-five pounds, all due to an outgrowth of the skin and subcutaneous cellular tissue.

For the relief of these tumors, the surgeon must call into requisition sorbefacient remedies, locally applied and administered internally; when these fail, the organ must be retrenched, or, if need be, excised, an operation which is, however, generally impracticable. Such, in a few words, are the principles of treatment.

Reports of Hospitals.

NOTES OF HOSPITAL PRACTICE.

By H. D. BULKLEY, M.D.,

PHYSICIAN OF NEW YORK HOSPITAL.

The Medical Department of the New York Hospital has furnished during the month of October a variety of interesting and instructive cases, some of which are thought worthy of record.

The different forms and varieties of malarial disease have formed a large share of the whole number of cases, though not so numerous nor so severe as during some past years. There have been fewer of those severe cases of congestive fever which are always so alarming, and a much smaller number of cases of that form of cachexia produced by the malarial poison, so characteristic of the effects of its protracted influence, and fewer cases of visceral enlargements from this cause than were so common in past years. Whether this is to be attributed to the smaller number of sailors engaged in the Southern trade than formerly, or whether they remain a shorter time on shore, or whether prophylactic means are more generally used, it is difficult to say.

But two cases of the congestive form of malarial fever have occurred during the month, and these not of the most severe form. Both yielded to quinine, at first by hypodermic injection, and afterward by mouth. This mode of using quinine is now the rule of the house, not only in such cases, but in simple intermittents, both quotidian and tertian; and it is seldom that it fails to prevent a paroxysm after entering the hospital, if there is sufficient time for its action. Two injections of four grains each, with an interval of two hours between them, are usually sufficient for this purpose. Quinine is then given by the mouth to prevent their return. This mode of treating different forms of malarious diseases has proved both effective and economical. Not the slightest unpleasant result has occurred in its use except in one instance, when an abscess formed, which caused but little trouble.

Not a single case of uncomplicated malarial disease has proved fatal during the month, and it is rare that patients with intermittents have had more than the second paroxysm after entering the hospital; and while it is true that the cases, as a whole, have been less severe than during former years, it is no less true that much of this success during this as well as the past season may fairly be attributed to the hypodermic use of quinine, first introduced into use in this hospital by my colleague, Dr. G. M. Smith. Instances have occurred in which it was necessary to administer these before the patient was taken from the carriage, to enable him to be brought safely into the ward, and perhaps again on his way into the ward. Preparations are made to administer quinia in solution in sulphuric ether, as lately recommended, but no trial of this form of giving it was made before the close of the month.

Atropia and morphia are also constantly introduced in the same way in appropriate cases, and without any inconvenience during the present month.

CHRONIC DYSENTERY.

Three cases of chronic dysentery and two of acute were treated with large doses of ipecac, and with good results. The first case was that of a man thirty-nine years of age, who had contracted the disease in the East Indies about two years previously, and who had been in the hospital over eight months. He averaged about eight or nine bloody stools in twenty-four hours. He took

seven boluses of ipecac, consisting of ten grains each, taking three daily, and at the end of eight or ten days had one or two evacuations each day, fæcal and without blood. The second, a man thirty years of age, first had dysentery in India about fourteen months ago, and when treated in this way, was having twelve to fifteen dysenteric stools a day. He took ten grains of ipecac three times a day, for ten days, and soon had only one or two fæcal and natural passages every twenty-four hours. This man had at the same time albuminuria. There was some œdema of the lower extremities. His urine contained no albumen at the time, though some had previously been found in it; but the microscope showed hyaline casts and kidney epithelium, and oxalates. After passing stools of this character some days, he had a characteristic clay-colored stool. He then took two more boluses, which had the effect the first twenty-four hours of producing a free bilious stool, and a few days afterward he was only passing one natural stool daily. The third case of this group was a man thirty-six years of age, who contracted the disease in China eighteen months before, and who was having twelve or more bloody and mucous stools in twenty-four hours. He took four doses of ipecac of ten grains each, and in a few days was passing one or two healthy stools in twenty-four hours. All these cases had been some time under treatment, and had taken a variety of remedies without any permanent benefit.

The first of the patients with acute dysentery was a man of thirty years of age, pale and somewhat cachectic, who had been suffering with the disease about three weeks before admission, and had about five or six passages daily, either mucous or bloody, or fæcal, more or less mingled with blood. He had taken calomel and opium at first, followed by opium alone, but with only temporary benefit. After several relapses he took four of the doses, containing ten grains each, of ipecac, and was completely relieved in a few days, and left the hospital at the end of sixteen days, entirely well.

The second case of acute dysentery was that of a man who had bloody stools, mingled with fæcal matter, who took two of the boluses, with the effect of producing free bilious discharges, and with entire relief.

A sixth patient, who took large doses of ipecac, was a man who had been in the hospital nearly four months, who was suffering under rather copious liquid stools, nearly natural in color, three or four in twenty hours, which were suspected to be tubercular in their character. In this case the result was negative, as might perhaps have been anticipated from the nature of the case. He took three boluses in the course of one day, and two on the following day. He vomited a little the first night, but not afterward. The first effect was an increase of the quantity and frequency of the discharges, with a decided bilious tinge, amounting to ten or twelve stools in the twenty-four hours. The stools then resumed their previous character, and their usual frequency. This mode of treatment was then discontinued, on the supposition that this was not a case in which it promised success.

It is perhaps worthy of notice, in passing, that the first of these patients on the list, the man who had contracted dysentery in India two years previously, had distinct attacks of rheumatism whenever the dysentery was alleviated, and that this alternation between these diseases had attracted his own attention, and led him to speak of it. This corresponds with the observations of some of the older writers, who considered them as analogous diseases, and both owing to a similar disordered state of the blood. This was the view entertained by Akenside, in his Commentary on Dysentery, who called this disease a rheumatism of the intestines, and said that rheumatism and dysentery made frequent transitions from one to the other. I cannot recall, however, any other instance of such a relation between them, nor is it mentioned by writers generally.

Ipecac given in these doses usually vomits two or three times very freely, after which it is tolerated by the stomach. The first of these patients only vomited after the first bolus; the second, the one with Bright's disease, vomited for two or three days after the last bolus was taken; the third vomited but very little, and only after the first bolus. The fourth patient (the first with subacute dysentery) vomited only after the first bolus; no note of the second (acute) case was taken on this point.

A mustard poultice was generally applied over the epigastric region for about fifteen minutes each time before a bolus was given, but not always. Laudanum was not given in any case before the exhibition of the ipecac, as recommended by Surgeon Docker, of Bengal, who was the first to bring this practice into notice, more especially in acute dysentery. This gentleman gave much larger doses of ipecac, sometimes as much as a drachm and a half at a time.

No sweating was produced by this mode of treatment in either of these cases.

The action of ipecac given in this way is decidedly cholagogue, its exhibition being soon followed by an abundant discharge of bile from the bowels, generally with a considerable quantity of fæcal matter, and a relief of the tenesmus and of all irritation; and it is doubtless to this action on the liver, and the free flow of bile which results from it, that its beneficial effects on the disease are to be attributed.

During the months of September and October, 1861, I treated three cases of chronic dysentery and one case of chronic diarrhœa with large doses of ipecac, and with such good results that I was induced to bring them before the New York County Medical Society, in a paper which was afterward published in the fourth volume of the American Medical Times. Of these cases, the disease had lasted in one three months, in a second five months, in a third four months, and in a fourth some months, without stating the exact time. The first of these patients was having fifteen to twenty stools in twenty-four hours at times; the second, eleven or twelve stools during the same period; and the third, sometimes as many as twenty, and seldom less than eight or ten. The number of stools in the fourth was not noted. The stools became nearly or quite natural, in the first case, at the end of eight or ten days; in the second, at the end of eight days; the third was in full convalescence in the course of a week. In the fourth case, so great a change was caused by a single dose of ten grains of ipecac, which produced neither nausea nor vomiting, that the patient left the hospital in a few days, after having been there under treatment for some months.

Dr. McKidd reports a case in the Edinburgh Medical Journal for July, 1861, in which a diarrhœa which had lasted ten years was almost entirely checked by the end of the first week by doses of twenty grains of ipecac (reduced in a few days to ten grains) every twelve hours; and it was this report which led to the trial of it in the preceding cases.

Three cases of albuminuria were treated during the month with the bichloride of mercury, and with satisfactory results. One of these was a boy about sixteen years of age, who had been suffering from the disease two or three years, who had never had scarlet fever, and whose disease could only be traced to exposure to alternations of temperature, and to damp and wet weather. He had granular and hyaline casts in his urine, and his body and limbs were much distended with fluid. The

dropsical effusion had subsided very much, his general condition was much improved, and when the urine was examined near the end of the month, no casts were found in it. In a second case, in which granular casts were found, this remedy was also found useful. The third case was that of a stout, well-developed man, who entered the hospital about the middle of the month, who was very much swollen, and whose urine contained a great abundance of albumen, and microscopical signs of an acute attack, and whose attack was directly produced by exposure to cold and wet. He was decidedly improving under the use of this remedy when he was discharged by request. The hot vapor bath had also been used in his case, but without marked effect. The dose of bichloride used in all the cases was one thirty-second part of a grain, in the compound tincture of gentian.

One case of chorea, of a rather mild form, in a boy about fourteen years of age, which had existed about two years, was treated with the bromide of potassium, in doses first of ten, and afterward of fifteen, increased to twenty grains, three times a day, but with little if any perceptible effect on the disease.

Rheumatism in its different varieties and forms was fully represented in the wards during the month, and there were a few cases of typhoid fever; and, as usual, some cases of delirium tremens—but we do not propose to extend our paper by remarks on these. The whole number of patients under treatment during the month was 219, and the total number of deaths, 8, or a little less than 4 per cent.

NEW YORK, November, 1867.

Progress of Medical Science.

GENTIAN ROOT AS A DILATOR.—Professor Winckel in Rostock recommends (Deutsche Klinik, 1867) the radix gentianæ rubræ as a new, simple, and cheap means of dilatation for surgical and gynecological purposes. His attention was first directed thereto by an article of John Jacob Haeberl, published in 1834, in which the author states that having operated for atresia uteri and desiring to keep open the orifice made by the trocar, he introduced a good, firm plug of radix gentianæ, and that on the following day he found no small difficulty in withdrawing the same, which had increased to twice its former size. According to Dr. Winckel's observations the gentian root has the following advantages over laminaria: 1st. Its cheapness, the ease with which it can be obtained, and the fact that the physician can so easily cut plugs and bougies of any size to suit his requirements. 2d. Its somewhat smaller power of absorption, as compared with laminaria, is compensated by our being able to obtain larger pieces of it (one and one-half to two inches in diameter) so that it can be used for the dilatation of openings already too large for laminaria. 3d. The fact of its *remaining free from smell* constitutes an immense advantage, for even laminaria, though in a much less degree than sponge-tents, often becomes quite fœtid.

The radix gentianæ may therefore be used with special advantage in strictures of the vulva, vagina, and uterus; for tamponing the uterus in smaller hæmorrhages, for the induction of abortion, for dilatation after operations for atresia of the genital organs. Whether it is also applicable to stricture of the urethra, to affections of the lachrymal ducts, etc., remains to be seen.—*All. Med. C. Zig.* 1867.—*Memorabilien.*

REMOVAL OF THE SCAPULA, HALF OF THE CLAVICLE, AND THE WHOLE ARM; DEATH ON THE THIRD DAY.—Sir William Fergusson lately performed this operation upon a patient in King's College, London, it being somewhat similar to the one done by him two years ago, and reported in our columns, this making the second one of the kind performed in London. The following account of the case is taken from the London *Lancet:*

Josiah B——, aged forty, married, late of Queens land, New South Wales, was admitted into the hospital on the seventh of October last, with a large osteo-sarcomatous tumor, involving the left scapula, shoulder-joint, and adjacent parts. Two years ago he fell on the left shoulder and cut it open against a sharp edge of wood. The wound healed in a fortnight, leaving a cicatrix, which is now visible. Two months afterward he noticed that the shoulder was becoming painful; and, in three months, that a tumor was appearing. It increased rapidly for six months. He went to Sydney, where he was advised to come to England. The size of the tumor remained stationary from the time of his visit to Sydney till two months ago, since which time it has again increased rapidly. He has had a numbing pain in the shoulder ever since the commencement. This pain has been worse of late. He has always enjoyed robust health. He says that his father died after the removal of a tumor from the back. He is to all appearances a strong man; and, with the exception of the tumor, in a good state of health. There is a large tumor in the left scapular region. It is smooth, in parts very hard, giving a bony sensation. The skin is freely movable over it, and perfectly free from disease. It moves easily with the scapula; but is immovable in its deep attachments. It occupies the whole of the space behind the scapula, and takes three palms of the hand to cover it. It also projects downward into the axilla. Here it is very hard, and the covering of skin is thinner than elsewhere. The growth goes forward under the clavicle, but does not go above it into the clavicular region of the neck. The subclavian can be readily compressed against the first rib. The arm is freely movable backward and forward, going with the scapula, but it cannot be directly abducted.

The following were the chief steps of the operation, which was brilliantly performed before a crowded theatre. The patient, under the influence of chloroform, was placed on his right side, well over to the right edge of the table. Mr. Wood compressed the subclavian artery. Mr. Henry Smith assisted on the right, and Mr. Trevor, the house-surgeon, on the left side. Sir William stood on the right side. The first incision was over the outer third of the clavicle, which was sawn through; then a long, sweeping cut from this point, curving down in front of the shoulder, round the arm, over the deltoid, to the inferior angle of the scapula. The shoulder-joint was found to be involved, the humerus being almost immovable. The flaps were then dissected off from the scapula, and the muscles divided along the upper and ventral borders of this bone, which, with the arm, was well tilted forward, and the knife carried round with a circular sweep to the clavicle, whence the incision had first started—the important vessels and nerves being divided, so to speak, by the last cut. The flaps were then sponged, and the main vessel and others secured. Mr. Wood had the subclavian so well under control that there was no bleeding from it, and very little from the smaller arteries; the man lost but six ounces of blood at most. Some spicula of bone were dissected from the posterior flap, and a piece sawn from the outer end of the clavicle, which was too long. The flaps, which were abundant, were brought together by sutures, and water-dressing and strapping applied. The man was under the influence of chloroform during the whole of the operation, but seemed to feel a shock when the

main vessels and nerves were divided. The tumor, which was of an osteo-sarcomatous nature, was sent to the Royal College of Surgeons. The patient expired at the end of the third day, from the combined effects of the shock of the operation, and the existence of fatty heart, fatty kidney, and fatty liver.

Fractures at the Hip; the Nature of the Lesion, and its Treatment.—Dr. H. G. Davis, in an interesting chapter on fractures (*Conservative Surgery*), takes occasion to refer to the characters of intra and extra capsular fractures. After alluding to the strength of the neck of the femur, and its capability of bearing any amount of weight from below upward, he asserts that when the force is applied in the opposite direction a strain is brought upon the cervix in its most defenceless position. This is accounted for by the degree of obliquity of the neck of the bone, and the direction of the cancelli that support the articulating head. One set of these fibres, arranged in the form of a cone, with the base resting upon the buttress of the cervix, run upward toward the head of the bone, in the direction of the line of the pressure, while a few fibres are arranged in a similar manner upon the upper portion of the neck, but with the difference that their base is toward the head of the bone. The intermediate fibres between these two cones are more or less interlaced.

It is this direction of these braces of support to the head of the bone that mechanically disposes in a fracture a portion of the bone to split in a more or less oblique direction. The break commences upon the upper side, and extends transversely until it reaches a point near its lower surface, where the resistance will be least in a longitudinal direction. Hence it will split in a wedge-shape, the apex of which may or may not extend under the capsular ligament, retaining its connection with the neck of the bone, through both the capsular ligament and the periosteum. When the force is applied in an opposite direction the direction of the fracture will be different. In both instances the fracture at first takes place transversely, and after following such a course through the greater thickness of the neck the line of fracture is deflected in the course of one or other of the oblique fibres, and split off, so to speak. It is this split portion which, according to Dr. Davis, bears such an important relation to the proper treatment of fractures at the hip-joint. If the parts after such injuries are handled with care, and the surgeon is not over-anxious to get crepitus, the necessary connections of this wedge-shaped splinter and the periosteum will be preserved, thus augmenting the chances of bony union.

In support of this view he not only quotes examples in which the fracture has taken this course, but refers to the fact that in a large number of cases there is at first but a slight shortening of the limb; that occasionally locomotion is performed for some days, when shortening takes place suddenly. He also alludes to the fact that it not unfrequently happens that when slight shortening exists at first, and the limb is manipulated, extreme shortening occurs, and crepitus is only then secured. He considers it best to run the risk of making a correct diagnosis by giving the patient the benefit of a doubt, and employing the continuous elastic extension. If at the end of a few days the urgent symptoms subside, as in the case of a severe bruise, a cautious use of the injured limb may be allowed, while the treatment by the elastic extension is equally applicable to both. He is willing to admit that bony union is rather a forlorn hope, but he believes that the only chances that it may occur are centred in care in conducting the necessary examination of the limb. If, however, a surgeon is determined to get crepitus in every case when there is reason to suspect that the continuity of the bone is not absolutely destroyed, no union of the parts can necessarily occur. The shaft of the femur is drawn up by the muscles, and when a reduction is attempted, the lower edge of the trochanteric portion impinges against that of the neck, and as the only attachment of the head and neck to the pelvis is by the round ligament, they rotate upon it, thus bringing the upper outside portion of the cervix, and perhaps a part of the head, in apposition to the fractured face upon the shaft. Then the head of the bone, from the scanty nourishment it obtains by means of the round ligament, soon falls a prey to absorption, the limb becomes permanently shortened, and the patient incurably lamed.

The method of treatment pursued by Dr. Davis in these cases is similar to that of continuous extension by the weight and pulley, as recommended by him in the treatment of morbus coxarius; the idea being to keep the parts in their natural relations, and the limb in its normal length, giving nature the best possible chance.

If these views prove to be correct, and they certainly appear reasonable, Dr. Davis has, in a portion of the cases of inter-capsular fracture, relieved the profession from what has heretofore been considered an insurmountable difficulty, and has furnished strong evidence of the necessity for a thorough investigation into the "mechanical causes operating injuriously, both in health and disease."

Ointment for Pruritus Vulvæ.—℞. Pure (or camphorated) lard, 60 grammes; citr. oint. 3 grammes. M. Rub a small piece on the parts while in bed. Should the pruritus resist this topical application, analyze the urine. If glucosuria should be found to exist, add to general treatment M. Bouchardat's unguent, to wit:

℞. Potass. carbon. 100 grammes; tinct. benzoin, 50 grammes. M.

M. Adrian's Formulas for tar preparations are, viz.:

Emuls. of Vegetable Tar.

℞.	Choice tar, . . .	10	grammes.
	Yellow of one egg, or .	15	"
	Water, ...	75	"
		100	grammes.

Glycerined Tar.

℞.	Choice tar, . . .	15	grammes.
	Yellow of one egg, or .	15	"
	Glycerine, . . .	70	"

(1 grain equals 18 grammes.—Ed.)

Spina Bifida.—Dr. Fazeuilhe (of Rieumes) having to deal, in the case of a new-born child, with a voluminous spina bifida, and adherent by a pedicle of three centimetres in diameter, did not hesitate, after evacuating with a trocar the limpid serosity contained in the tumor, to excise it, following the surgical method of M. Dubourg (of Marmande) as given in two successful cases, reported in the *Journal de Médicine Pratique*. In chronicling this new audacity the *Journal* rightly recalls the reserve which men of experience, such as MM. Guersant and Giraldes, held in regard to curative means employed in spina bifida. M. Guersant did not believe at all in the radical cure of this affection; and among the sequelæ to the operation, M. Giraldes determined among other things a case of hydrocephalus.

M. Fazeuilhe is, to appearances, too confident. His example, at all events, should not be followed in every case.—*La France Medicale*, Oct. 16, 1867.

Maissonneuve, of Paris, recommends for the radical cure of varicocele, coagulating injections of the perchloride of iron.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

"IS HE RELIABLE?"

IT seems strange, at first sight, that as the whole object of science is truth, there should be any question in regard to so-called scientific facts. All of us are, however, aware that statements intended to be scientific are constantly open to every conceivable doubt as to their authenticity. How fashionable has it become, when any startling assertion is made by a professional brother, for one to ask the other, "Is he reliable?"

The question is a perfectly natural one, for it is necessitated by the circumstances of the case. Whatever may be the implication of want of truth on the part of the observer, the real cause for doubt rests upon the conviction that the assertions are too apt to be exaggerated, and savor of a one-ideaism. The majority of men who engross themselves in one pursuit, or in one particular department of a calling, seem incapable of resisting the temptation of presuming it paramount to everything else. They get, so to speak, in that habit of mind in which their imaginative faculties outgrow their reason and common sense; and, while they have no desire to overreach the truth, seem incapable of sticking to it. This curious psychological state is strikingly illustrated in a story told by a celebrated humorous writer.

It appears that a traveller, who was very anxious to take a stage very early in the morning, put up the night before at a roadside tavern near the station, and left instructions with the porter to be waked in time. He then retired with the full assurance that his wishes would be complied with, and settled himself for a comfortable night's rest. But, alas! in the still small hours he was aroused by an ominous whisper through his key-hole, "Mister, the stage has just passed." This piece of intelligence was sufficient to expedite his toilet in an astonishing manner; his legs were thrust into his pants, his boots were stamped on, his coat quickly found its place upon his back, and, with satchel in hand, he was soon in readiness, along with his informer, for some violent exercise in the effort to overtake the vehicle at its stopping-place. Fences were cleared, ditches leaped, and, by dint of much running, the station was reached. On inquiry, however, it was discovered that the carriage was not due for two hours. The indignant traveller turned upon his companion, and charged him with the perpetration of a rather serious joke. The answer which he received was: "You see, Mister, from thinking of the coach, from expecting it, from wishing for it, and dreaming on it, I thought I heer'd it!"

There is no difficulty in meeting with cases parallel to this in scientific investigations; and we should be as ready to exercise forgiveness toward such observers, as we will suppose, "for the argument's sake," was the victimized traveller towards his guide. If any individual coaxes himself to believe that his particular method of treatment is the *ne plus ultra* of everything that is desirable, he is very easily tempted to conform his theory to facts, rather than the facts to the theory. There is in such persons a constant tendency to exaggerate every element that bolsters up their views, and to make light of every other circumstance tending to refute them. They are convinced that an operation by a particular method must succeed, and will hardly believe that their expectations have not been realized, even when the patient is dead.

The power of the imagination over other faculties is also as marked as it is subtle, even when an investigator shows a determination to guard conscientiously against every source of error. Every medical student knows this full well from personal experience, especially in the study of those branches which require a more than ordinary acuteness of perception. We need not refer here to more than two of these, auscultation and microscopy. If he listens for a particular sound in the chest, in the belief that it is there, he invariably hears it, though it may be entirely absent. Under the microscope he makes out delicate definitions, which cannot possibly be developed by the lens of the power he is using. All this, it is well known, does not depend entirely upon a want of sufficient acuteness in hearing in the one case, or of focal adaptation in the other.

But there is another class of observers who are less conscientious, and who are not only chicken-hearted about telling the plain truth, but who sometimes wilfully pervert everything to meet their ends. The supposition that this is the case, is the only rational one for explaining the many discrepancies and glaring untruths that are scattered throughout their works. They claim for their personal experience more than is by the greatest stretch of imagination their due, and speak of successes which are to every reasoning mind simply impossible. These impostors are self-conceited enough to suppose that their trickeries are not transparent; and there is no consideration of justice on their part that will tempt them to mend their ways.

True science, dealing as it does with stubborn facts, with laws that are unchangeable, and with conclusions that are logically irrevocable, can give no quarter to speculations however ingenious or captivating, and every element of the imagination must necessarily be left out. We admit, that in order to follow the tortu-

osities of this thorny path, much sacrifice of mere opinion is necessary, many pleasing and tempting deductions must be overthrown, and everything in the shape of a prejudice for or against any particular view be resolutely combated. (When so much is required of the would-be votaries to this shrine, is it a wonder that so many grow weary, and fall out by the way?)

But on the other hand, there are multitudes of honest workers who have conquered every prejudice for this or that theory, who look through a lens without a single aberration, and who are willing to labor for the fascination of discovering truth in its purity. These are they who are ever ready to report unsuccessful results, errors in diagnosis, and mistakes of every kind; who, in the true interests of science, are not only searching after pleasant paths, but are willing to point out the pitfalls which they have escaped and fallen into. Observations from such men are always reliable, and their deductions are always sound. Their cases are accurately detailed, every point concerning which there may be a doubt is clearly presented, and nothing is left to be desired in the way of completeness.

It is preposterous for any one to suppose that unless he fairly earns a reputation for reliability by an honest endeavor to adhere to simple facts, untinctured by prejudice of any kind, that his works can endure.

The following out of this principle has given to us every illustrious name in medicine. Their works are handed down from past ages, not merely as curiosities in literature, but because of the manly and outspoken truths which they contain, truths which every recent observation serves only to confirm, and add new lustre to the fame of the writer. Some of the descriptions of disease by the ancient authors are, in fact, so accurate, that a literal translation of them would serve every purpose at the present day. How dangerous would it have been for such to have drawn on their imaginations, to have perverted facts and the like, when an army of uncompromising truth-seekers were waiting to prove their statements by the test-tube, the retort, the post-mortem knife, and the microscope!

UNDER Reports of Hospitals we propose, in addition to accounts of important cases, shortly to present a series of articles descriptive of the practice of the various hospitals of New York in the more common affections, incorporating such clinical teachings of the attending physicians and surgeons as may serve to illustrate the subjects treated. We hope to make this department of the RECORD especially valuable to those of its readers who have not the opportunity of personally availing themselves of the immense hospital advantages our city affords.

OWING to the unusual press of matter we have been compelled to defer the publication of several original articles of singular merit, among which may be mentioned one by Professor Salisbury, of Cleveland, Ohio, which is profusely illustrated, one by Dr. Rogers on an important subject, and an interesting report of a case by Dr. Hachenberg, of Hudson.

THE full attendance at the various societies, and the great amount of interest manifested in the discussion of the various medical topics, are very significant of an increase among our active workers. There is nothing that conduces so surely to mutual improvement and an increase of our knowledge than such associations, and we are gratified to chronicle the fact that so many of them are so well patronized.

Reviews and Notices of Books.

CATALOGUE OF THE U. S. ARMY MEDICAL MUSEUM. Prepared under the Direction of the Surgeon-General, U. S. Army. Washington: Government Printing Office. 1866-7. Pp. 961.

SURGEON-GENERAL BARNES deals in surprises, and of the most agreeable kind. The very modest title of "Catalogue" conveys but a faint idea of the interest or value inherent in the closely-printed and profusely illustrated volume before us. It is indeed something more than a catalogue, since the numbered specimen and name of contributor is invariably accompanied by a succinct description and history, calculated to satisfy any reasonable amount of curiosity regarding results. As a careful compilation, seeking to record for the benefit of science duly authenticated facts, it is a monument of labor, destined never to be too highly appreciated. The fortunate possessor of this contribution to the history of the late contest might well hesitate to exchange positions with the spectator in the museum itself, since he is able to command at his convenience the studied details and the wealth of facts without the bewilderment of artistic embellishments and the embarrassment regarding the point of commencement.

About three-fourths of the Catalogue, as was to have been expected, is devoted to the department of surgery. The general scope of this grand division may be best gathered from the following summary of diseases and injuries, as given in the table of contents: (1) Cranium; (2) Face; (3) Vertebræ and Cord; (4) Thoracic Parietes; (5) Shoulder-joint; (6) Shaft of Humerus; (7) Elbow-joint; (8) Shafts of Radius and Ulna; (9) Carpus; (10) Hand; (11) Pelvis; (12) Hip-joint; (13) Shaft of Femur; (14) Knee-joint; (15) Shafts of Tibia and Fibula; (16) Tarsus; (17) Foot; (18) Organs of Circulation; (19) Organs of Respiration; (20) Abdominal Viscera, etc.; (21) Results of Operations on Soft Tissues; (22) Injuries to Soft Tissues not Viscera; (23) Erysipelas, etc.; (24) Tumors; (25) Casts; (26) Photographs and Drawings; (27) Weapons and Projectiles; (28) Materia Chirurgica; (29) Miscellaneous Articles; (30) Lower Animals; Index of Contributors and Index of Specimens.

Each one of these sections is properly subdivided; as, for example, in the case of "Injuries and Diseases of the Face, including the Organs of Vision, Smell, and Taste," the subject is treated with reference to gunshot injuries, injuries not caused by gunshot, and diseases and their results. These gunshot injuries are then classified as being "Of the Bones of the Face, not including the Lower Jaw; Of the Lower Jaw; Of the Eye and of the Tongue." Another subdivision finally disposes of the "Gunshot Injuries of the Bones of the Face not including the Lower-jaw," under the captions of

'*Fractures not Primarily Fatal; Fractures without Operations, Secondarily Fatal; Results of Operations; Results of Exfoliations; Fractures and Dislocations indirectly produced which are not in themselves Fatal.*" We have selected the above at random, and, as the reader will perceive, have not pursued the matter down to the necessary minutiæ; but we trust that enough has been given to impart an idea of the general plan of the work.

To Dr. Alfred A. Woodhull, Assistant Surgeon and Brevet Major, U.S.A., is due the honor of having prepared the surgical portion of the Catalogue. His descriptions of the specimens are singularly graphic, pithy, and exhaustive. As far as condensed expression is concerned they approach the suggestiveness of Scriptural texts. And when we consider the temptations to amplify, this is indeed a rare merit.

When we say that Dr. Woodward has grouped the objects of interest for the medical department of the museum, we know that our readers will be well assured of the completeness, the judgment, and the taste displayed in the execution of his onerous, and, as we surmise, pleasant task. An accomplished pathologist and an accurate observer, he has made the most of his opportunity, and reflected no little lustre upon the hard-working and not enough appreciated medical department of our army. Much has been required, but more accomplished.

The Table of Contents will give better than any extended *critique*, an idea of this division of the work. Chapter I. (Nervous System) introduces us to specimens illustrating lesions, etc., of the *brain*, *membranes of the brain*, *pineal gland*, *bloodvessels of encephalon* and *spinal cord*. Chapter II. (Organs of Circulation) presents us with the results of autopsies, exhibiting morbific changes and congenital anomalies of *the heart*, *arteries and veins*, *lymphatic glands*, and *thyroid gland*. Chapter III. (Respiratory Organs) is rich in dissections of the *air-passages*, the *lungs*, and *pleuræ*. Chapter IV. (Digestive Organs) adds not a little to our knowledge of the diseases of the *mouth*, *pharynx*, and *œsophagus*, the *stomach*, *intestinal canal*, *peritoneum*, and *omentum*, *liver*, *pancreas*, and *spleen*. Chapter V. (Urino-genital Organs) is quite suggestive. It is subdivided under the head of *kidneys*, *suprarenal capsule*, *urinary passages*, and *bladder*, *male organs of generation*, *female organs of generation*, and *fœtus*. Chapter VI. (Organs of Locomotion) is disposed of under two sections—*muscles and fascia*, *bones and joints*. Chapter VII. (Integument) and Chapter VIII. (Anomalies and Monstrosities), followed by a copious index, close this portion of the Catalogue.

The embellishments are also fine. No. 98, from a specimen just above the ileo-cœcal valve, exhibits in a very artistic manner, the appearance of the ileum, with enlarged follicles, etc. No. 280, taken from a case diagnosticated as typhus, points out "the solitary follicles, enlarged to size of small shot, and projecting as polypoid tumors from surface of mucous membrane; at the apices of many of these tumors are one or more small points of ulceration." No. 468 very ably and elegantly reproduces "A portion of descending colon considerably thickened, and presenting numerous follicular ulcers, varying in size from mere points to three lines in diameter;" and No. 224, follicular ulcers of the colon, which have degenerated into "vast eroding excavations." These complete the illustrations of the medical section.

Another portion of this magnificent publication is devoted to an enumeration and description of microscopical specimens. This department has been very wisely entrusted to Assistant Surgeon Edward Curtis, who has achieved an enviable reputation for indefatigability and fidelity. We are told that a large majority of the specimens have been prepared in the microscopical department of the museum, the greater part by Acting Assistant Surgeon J. C. W. Kennon, U. S. Army; the remainder by Assistant Surgeon Edward Curtis, U. S. Army, and Hospital Steward E. M. Schaeffer, U. S. Army. Professor Joseph Hyrtl, of Vienna, Austria, is also represented by a number of "opaque fine injections in various colors to show the arrangement of the capillaries in the different structures of the body." These are mounted dry.

The microscopical section of the museum is conveniently subdivided; its objects for inspection being classified as "Mounted Preparations for the Microscope;" "Photographic Negatives of Microscopic Objects," and "Photo-micrographs presented to the Museum."

To say that the wealth of the museum in this respect is enormous, would give but a faint idea of the extent or completeness of the collection. Aside from the physiological specimens, which are derived from almost every family in the animal scale, pathological anatomy may here be advantageously studied by its most enthusiastic votaries.

Photo-micrography has been well worked up. We have illustrations of the apparatus and descriptions of the process, with a reason for every step taken, which to the scientific operator cannot be otherwise than exceedingly valuable. Dr. R. L. Maddox, of Southampton, England; Prof. Joseph Gerlach, of Erlangen, Bavaria; Dr. C. F. Crehore, of Boston, Mass.; Mr. J. H. Woodworth, of Dublin, Ireland, and a few others are credited with specimens presented.

The Catalogue, as a whole, well assures us that the Surgeon-General has conscientiously devoted his energies to the task, which we are proud to say we have every reason to believe has been performed without reluctance, and entirely in the interest of science. The work of compilation, attended as it is with the necessity of elimination and condensation, though tedious we can now very readily see has steadily progressed, and that the condemnatory resolutions introduced before the American Medical Association at its last meeting were, to say the least, injudicious, if not an unwarrantable reflection upon a faithful public officer. That they did not prevail was due to the appreciation in which that officer is held by the profession, as well as to the fact that of the members of that Convention, not a few were content "to keep their souls in patience," well satisfied that the future would vindicate the wisdom of the order denying promiscuous reference to documents, even on the part of authors themselves.

TRANSACTIONS OF THE AMERICAN MEDICAL ASSOCIATION. Instituted 1847. Vol. xviii. Phila.: 1867. 8vo, pp. 548.

THE Transactions for the present year is filled with interesting and practical matter for the profession at large, and reflects credit upon the last year's doings of this representative body. Our readers have already been presented with a full report of the proceedings in Cincinnati, so that there is no need for our referring to the contents of that portion of the volume occupied by them, except to state that the report is carefully drawn up by the permanent secretary. We have, however, more to do with the many elaborate and well-written papers which are contained in it. The address by the president, Dr. H. F. Askew, of Delaware, is a bold and manly expression of opinion concerning the present status of our art, and the radical methods to be adopted to raise its standard. Dr. Stephen Rogers' paper on extra-uterine fœtation has contained in it some original views in reference to the method of diagnosticating its existence, as well as the treatment of the attendant hæmorrhage. He asserts in substance

that colicky pains in the hypogastric region, attended with a sanguinolent discharge per vaginam, are almost pathognomonic, all other things being equal, of extra-uterine pregnancy; and as statistics have failed to prove to him that a single case of hæmorrhage accompanying this condition ever recovered, he advises abdominal section and the securing of the vessel. His arguments in support of this latter view are well put, and deserve the consideration of every interested party. Dr. Taylor's paper on heart diseases in the army is very practical in its character, and refers principally to the frequency with which dilatation of the left ventricle is met among those who are exposed to great fatigue and privation. Dr. Hamill's report on the medical topography of Illinois is a valuable statistical contribution to sanitary science. Its extreme length will perhaps interfere with a general reading. Dr. Hildreth's observations on the application of belladonna to diseases of the cornea will be read with interest by those whose practice tends towards ophthalmology. The report on the use of plaster of Paris bandages, by Dr. J. L. Little, is a praiseworthy attempt to bring to the notice of his brethren a very useful practice; but, as our readers are already acquainted, in a measure, with the gentleman's views, we pass on. Dr. B. Howard contributes a short and extremely valuable paper upon a new method of treating varicose veins, by ligation with silver wire in the first place, and depletion of the ligated vessels in the second place. The plan is a commendable one, and deserves a trial. The report of the committee on ligation of the subclavian, by Dr. Parker, gives evidence of much research and careful study. There is contained in it a tabulated statement of one hundred and fifty-seven cases; but the chief value of the report is centred in the conclusions which a faithful study of the statistics of the operation has afforded. The same may be said of a well written and elaborated article upon the hip-joint operations during the late civil war, by Dr. Paul F. Eve. The report upon the rank of the naval medical staff is full of significant facts, which are well presented and conclusive as to the necessity of radical reforms in that department. The report on American medical necrology, we are sorry to say, is by no means complete, and in many portions of it there is evidence of an undue haste in its preparation. The report on medical education presents no new facts, aside from those already referred to in our columns, when discussing the subject. Dr. Post's report on medical literature is well and tastefully written, and gives all the desired facts with a charming and commendable conciseness. Dr. Isaac Ray's paper on the progress of knowledge in insanity is full of sound reasoning and useful and common-sense suggestions. Lastly, the two prize-essays, by Dr. Black, on the cause of intermittent and remittent fever, and by Dr. Pallen on the treatment of certain uterine abnormities, are worthy of particular mention for the amount of study and work which each gives evidence of. Dr. Black's views are to a certain extent original, and the plain and common-sense arguments which he urges in their support will strongly appeal to the judgment of the profession for widespread adoption. Dr. Pallen has also given us many interesting facts bearing upon his subject, but his plans of treatment for uterine affections can hardly be recommended for safety. The Western women may be proof against bad results from the operations which he proposes; but our Eastern females certainly lack much of that necessary stamina.

The meetings of the different sections are by no means represented as they should be. In them, many of the papers referred to in the volume were fully discussed, yet we have in the reports of their respective secretaries the merest mention of such facts. This should not be so. In the interest of the section, no gentleman should accept the office of secretary without a full appreciation of the responsibility attending it, and should in one and all cases be prepared to give a decently full report of the remarks made thereat.

The treasurer, in his annual report, tells us that the association is in debt for the publication of its transactions. This is a grave reflection upon the character of the body, in not liberally supporting every laudable effort to place before its members much valuable material. We are in hopes that the sale of the present volume may exceed its predecessors in just so much as it does in literary and scientific merit.

THE PRACTICE OF MEDICINE AND SURGERY APPLIED TO THE DISEASES AND ACCIDENTS INCIDENT TO WOMEN. By WM. H. BYFORD, A.M., M.D. Author of a Treatise on Chronic Inflammation and Displacements of the Unimpregnated Uterus, etc. Second edition, enlarged. Phila.: Lindsay & Blakiston. 8vo., pp. 616.

PROF. BYFORD'S book may safely be said to fill a gap in a most important department of the healing art. The treatise is as complete a one as the present state of our science will admit of being written, and not only gives us the cases in which the knife is to be called into requisition, but fully discusses all those uterine ailments which are to be benefited by medical treatment. In this latter respect, the work has a peculiar value to every general practitioner. The author speaks from experience, evidently with the sole object of presenting his subject in a strictly impartial and scientific light. The present edition is much enlarged in point of matter contained in the work, although the volume itself is very little, if any, increased in bulk. We commend it to the diligent study of every practitioner and student, as a work calculated to inculcate sound principles, and lead to enlightened practice.

A BIENNIAL RETROSPECT OF MEDICINE, SURGERY, AND THEIR ALLIED SCIENCES. Edited by MR. H. POWER, DR. ANSTIE, MR. HOLMES, MR. THOMAS WINDSOR, DR. BARNES, and C. HILTON FAGGE, for the New Sydenham Society. Phila.: Lindsay & Blakiston. 1867. 8vo., pp. 496.

THIS volume, published under the auspices of the New Sydenham Society, now makes its welcome appearance bi-annually instead of yearly, as heretofore. It is the most carefully prepared retrospect with which we are acquainted. Each department is in charge of a gentleman of reputation, and everything is done to summarize, in a very readable way, all the more important advances in medicine over the globe. It is handsomely bound and elegantly printed.

HUFELAND'S ART OF PROLONGING LIFE. Edited by ERASMUS WILSON, F.R.S. Author of A New System of Human Anatomy, etc. From the last London edition. Philadelphia: Lindsay & Blakiston. 1867. 12mo., pp. 298.

THE Art of Prolonging Life was written more than half a century ago, by Christopher William Hufeland, a professor of medicine in the University of Jena, since which time, on account of a deserved popularity, it has gone through several German editions. As early as 1794, it was first translated into English, probably by the author himself. Although subsequent English translations have appeared since then, none could compare with the original one in elegance and exactness. Prof. Wilson has recently taken upon himself the task of editing the first translation, and adapting it to the wants of the present generation, and has been eminently successful in the endeavor.

In the present age of fast living, such a work as the

above has a novel interest. Founded as the statements are upon facts, they appeal, in trumpet tongues, to every man of common-sense. No one who reads it can quarrel with the author's intentions, even if he is not prepared to accept the conclusions. The relations of the moral to the physical nature are philosophically set forth, and the whole forms a complete though short treatise upon the several fundamental questions relating to the prolongation of life. He maintains that the duration of life in a being will be proportioned to the innate quantity of vital power, the greater or less firmness of its organs, the speedier or slower consumption, and perfect or imperfect restoration. When all these conditions exist, and are preserved by a reasonable amount of care on the part of the individual, the chances for exceeding the three score years and ten are proportionately great. This principle of preservation is one that is, however, hard to follow at the present day, as we are forced by all the external circumstances of our living to think faster, work with more rapidity, and worry more over the chances of success than did our forefathers, and in proportion as we increase the draught must we consume the fuel. Still, a happy medium can be consistently drawn between the two extremes, and by a proper observance of the relations of the physical to the moral element of our nature, many years of comfort and happiness may be added to our lot. If we are determined to burn our fuel rapidly, let us allow our vital energies to become recruited by rest, instead of adding to them the additional burden which unnecessary exciting excesses, improperly denominated pleasurable recreations, impose. The foundation of a prolonged life rests in the possession of a good digestion and a consequent excellent appetite, for all those who have attained a great age possessed these qualities to a remarkable degree, and retained them to the last. In nothing do the present generation pay more severely the penalty of civilization than in the deprivation of these inestimable blessings—a fact sufficiently explained by the increased mental excitement which we are subjected to, no less than in the trickeries of fancy cooking, and the great tendency of the teeth to premature decay.

The work is a charming one—the style is plain and unassuming, but is enriched by the soundest philosophy and the broadest common sense. The anecdotes of long-lived celebrities are well told, and no one can read the work for profit without gaining from it much that is entertaining and amusing. It is a book well calculated to win favor with the profession and the reading public.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, Nov. 27, 1867.

DR. H. B. SANDS, PRESIDENT, in the Chair.

RETENTION OF URINE BY IMPACTED CALCULI IN URETHRA.

DR. CUTTER stated that, two weeks before, he had been summoned to Boonton, N. J., the messenger bringing the intelligence that the father of Dr. Farran, of that place, had been suffering from retention of urine for forty-eight hours. The patient was seventy-three years of age, and weighed nearly two hundred and fifty pounds. On arriving at the place, Dr. Farran informed him that he had succeeded in introducing the catheter as far as the bulbous portion of the urethra, but could not go beyond it. A large-sized catheter was then introduced, and likewise a smaller one, but the point referred to could not be passed. Going back again to the large catheter, and the fingers supporting the scrotum, a hard lump was detected at the seat of the obstruction. The instrument was then withdrawn and a dressing forceps introduced into the urethra, with a view of grasping the foreign body and removing it. As this could not be done, perineal section was proposed and performed, when the obstruction was found to be an impacted calculus. As the sound could not be passed beyond the obstruction, the stone was pressed forward, and was then cut upon and removed. The operation was attended with immediate relief, it only being necessary to use the catheter once after the operation.

The calculus, which was of small size, showed three facets upon its surface, which proved the existence of two others in the bladder. One of these had been detected in the bladder on the occasion of passing the catheter after the completion of the operation.

DR. MARKOE, in this connection, stated, that five weeks ago he had operated during his clinic upon a similar case in a boy six and a half years old. One year before he saw the patient; he came home from school complaining of an inability to pass his water. A physician was called, who succeeded with difficulty in introducing the catheter and drawing off the urine. This retention recurred from time to time, sometimes allowing but a little water to be passed voluntarily, at other times the stoppage being complete. This went on for a long time, the attending physician passing a catheter whenever the urgency of the symptoms demanded it.

On being brought to the clinic a steel sound was introduced, when an obstruction was discovered in precisely the same situation as in Dr. Cutter's patient; said obstruction proving to be dependent upon a calculus. The attention being then directed to the perineum, and a solid body being felt in the situation referred to, and it being of an oblong shape, the doctor ventured to predict that it was occasioned by a slate-pencil, more especially as it had lodged there so long, permitting an instrument to pass by it when the bladder had been relieved.

Perineal section was performed, and a rounded calculus was removed instead of a slate-pencil, as was anticipated. The elongated, hardened mass felt through the scrotum was found due to the deposit of fibrinous material in the long diameter of the tumor. The case afterwards progressed favorably, the patient having no more trouble in the passage of his urine.

In answer to a question from Dr. Van Buren, Dr. Cutter stated that in his case the prostate was slightly enlarged.

PROBABLE GUNSHOT WOUND OF STOMACH.

DR. CUTTER next exhibited a specimen, the history of which, he was sorry to say, was not complete. It was a small pistol ball, very much the shape of a Minié rifle ball, removed from a boy fifteen years of age, who was accidentally shot by his father five years ago. The missile entered the umbilical region over the centre of the large pouch of the stomach, and apparently passed directly through the organ and lodged in the back. As the case belonged to Dr. J. F. Ward, of Newark, who had attended the case for a very long period, he was unable to say whether there had been vomiting or purging of blood after the accident or not.

DR. HAMILTON thought it very unsafe to record such a case, with such an imperfect history as one of perforation of the stomach by a ball. He thought that it was necessary, in order to establish the existence of such a wound, to have vomiting of blood, or a discharge of it per rectum, or the existence of a fistula in the stomach itself, and the discharge of its contents through the wound.

Dr. Howard stated that he had met with several flesh wounds produced by pistol bullets at short range, and had invariably found that they had healed by first attention. He did not think it improbable that a wound might be made in the stomach and yet close with equal rapidity, leaving hardly a vestige of its course afterwards.

Dr. Sayre stated that he had only seen one case of *bona fide* gunshot wound of the stomach, and that was in the person of Beverly Cole, of California. In that instance there was vomiting and purging of blood, and a discharge of the contents of the stomach through the wound. It was three years since he had seen the case, and the patient was now doing well.

Dr. Hewit remarked that the case referred to by Dr. Sayre had been under his immediate care, being assisted by Dr. Valentine Mott, Jr., and Dr. C. S. Tripler, and that the symptoms were as Dr. Sayre had related them, except that there was no discharge of the contents of the stomach through the wound.

Dr. Sayre stated that he had merely reported the symptoms as they were detailed to him by the patient some time after the accident.

CANCEROUS TESTICLE.

Dr. Hewit presented a specimen of cancerous testicle, of which the following is a history:

On the 7th of the present month I was requested by Dr. Wright, of East New York, to see a case of suspected organic disease of the testicle, in the person of S. M. A. F. F. The following history was elicited:

The patient was forty-six years of age, a farmer and fisherman by turns, descended from a healthy and long-lived ancestry, born and raised in the immediate neighborhood, temperate, frugal, and chaste.

At the age of eleven he injured the right testicle in crossing a fence. Slight inflammation followed, and the groin remained from that time permanently enlarged, and sensibly harder than its fellow. No other noticeable circumstance was observed. At twenty-two years of age he married a healthy woman, and had a family of five children. Sixteen years ago he suffered an accidental bruise of the affected part, and it began to increase slowly in size and hardness, and to make its diseased condition manifest by occasional flashes of pain, and the irritation and inconvenience of its weight and bulk.

He continued, however, to pursue his occupations. The history from the time specified indicates progressive diminution (but not abolition) of sexual desire and power, and at a recent period the circumstance of acute pain in the act of emission. An examination revealed an elastic, symmetrical enlargement of the size of an ostrich egg, red, tender, and painful, with the sound testicle firmly compressed against the left external ring.

Diagnosis—Hydrocele, with malignant degeneration of the gland. Advice, extirpation.

Accordingly, on the 12th inst., I proceeded to the operation. Ether was cleverly administered by Mr. L. P. G. Gouley, and I punctured the sac and drew off about half a pint of serum. I was then enabled to examine the organ more carefully, with the result of confirming the view originally taken, and immediately proceeded with the ablation.

A Case of Traumatic Tetanus successfully treated by the Ordeal Bean of Calabar, is reported by Mr. A. Campbell, L.R.C.S., Edinburgh, in a recent number of the *Lancet*. One-eighth of a grain of extract was administered every half hour at first, and the result of relaxing the contracted muscles was soon obtained.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 2, 1867.

Dr. E. R. Peaslee, President, in the Chair.

REPEATED PRESCRIPTIONS.

The following preamble and resolutions, reported from the Comitia Minora, were adopted unanimously:

Whereas, The attention of this Society has been called to the repetition of prescriptions, containing active ingredients, by druggists, without the written order of physicians; and whereas serious consequences to patients are liable thus to ensue; therefore

Resolved, That we respectfully request the druggists of this city not to repeat such a prescription without the written order of the physician, he being the only competent judge of the propriety or necessity of such renewal.

Resolved, That a copy of these resolutions be sent to the druggists in this city.

MEDICAL INTELLIGENCE.

Among the topics embraced in the report of the Committee on Medical Intelligence were: Dr. Salisbury's article upon the discovery of a new algoid vegetation in chancroid; with Diday's view that all venereal diseases are of parasitic origin. The report of a committee of physicians at Florence, that syphilis cannot be communicated to animals; and the opposite conclusion maintained in a report lately presented to the Paris Society of Medicine. An account of the recent investigations concerning the period after menstruation during which conception is possible; of a new operation for relief of deafness, consisting in excision of the handle of the malleus, by the aid of the parabolic otoscope; and of the trial of acupressure in a case of subclavian aneurism.

HISTORY OF UTERINE PATHOLOGY.

Dr. T. G. Thomas read a paper upon the above subject, of which we give no abstract, as it will soon be published.

Dr. Peaslee said the Society was under deep obligation for the elaborate essay just read, and he hoped to see such papers presented more frequently. Our practice must be based upon our pathology; those discussions are most truly "practical" which give us comprehensive views of this; and for the attainment of such views historical investigation is essential. Though it is only within the last twenty-five years that uterine pathology can properly be said to have existed, yet it is surely of no slight import to know that the speculum was in use a century ago. He would allude to two or three points in the pathology and practice of the last twenty-five years. The lecturer had mentioned the prominent theories upon the subject, and he would refer especially to those of Bennett and Velpeau, who have exerted so powerful an influence in determining the present form of uterine pathology. The former maintained that the great majority (87 per cent.) of displacements are due to antecedent inflammation, the latter that in eighteen cases out of twenty the inflammation is caused by the displacement. Among adherents to the former, caustic is the great remedy, while Velpeau's disciples treat almost every case with some kind of mechanical support. Hence we had two, or he might say three, representative men in uterine practice: first, Bennett, with his caustic; second, Hodge, of Philadelphia, who pushed Velpeau's theory to its limit, and often used supporters (as he directly states) even where no displacement was found; and third, Sims, who, taking a different view still, that most uterine diseases depend upon some ob-

struction of the cervical canal, had given great prominence to operations upon the cervix. Doubtless each of these views required modification, though each had done much to advance true science. All innovators are apt to be extremists, yet we honor them none the less for their substantial additions to our knowledge. We think we have now learned the particular class of cases in which caustic is advisable, and we reserve it for such; while to mechanical support we assign its own province. Beyond question it will be the same with the view just now most fashionable, and the time will come when operations upon the cervix will be more rarely performed.

NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, Dec. 18, 1867.

DR. ALFRED C. POST, PRESIDENT, in the Chair.

ANNIVERSARY DISCOURSE.

DR. STEPHEN SMITH delivered the Anniversary Discourse, in which he gave a resumé of the condition of surgery in the metropolis, extending from a period of some two hundred years ago, to about the beginning of the present century. The discourse was interspersed with sketches and reminiscences of leading practitioners, among the most elaborate of which was a memoir of Dr. John Jones, Professor of Surgery in King's College, who died in 1791.

A copy of the discourse was requested, by a vote of the Academy, for publication.

The President announced that the Academy would be convened on the succeeding evening, to listen to a paper by Professor Horatio R. Storer, of Boston, Mass.

The Academy then adjourned.

NEW YORK MEDICO-LEGAL SOCIETY.

STATED MEETING, Nov. 5, 1867.

DR. T. C. FINNELL, PRESIDENT, in the Chair.

A CASE OF PERITONITIS, CAUSED BY LACERATION OF UTERUS BY SOUND.

DR. NEWMAN detailed the following case: A medical friend was summoned on Monday, Oct. 27th, to attend a woman four and a half months pregnant, who had been in labor thirty hours. She attributed her miscarriage to a fright got by collision with a boy on Broadway, and to a good deal of walking and excitement in Brooklyn. When he arrived, he found the external os dilated, the internal constricted, and the head of the fœtus presenting. On visiting her the following day at four o'clock, and finding no progress made, while the symptoms indicated increasing debility, he inserted Barnes's uterine dilator. But this proving ineffectual, he introduced a uterine sound, guided and protected by his index finger, with which he separated the membranes, first on one side, and then, after its withdrawal and reintroduction with the same care, on the other. By six o'clock of that same evening a dead fœtus was born. The placenta and membranes came away without difficulty; the former presenting to the eye the appearance of fatty degeneration. Immediately after this she was seized with a rigor, and the next day had the symptoms of violent peritonitis, which terminated fatally the following Saturday.

DR. BAHAN reported the result of the autopsy of the above case held the day following death. The abdominal cavity presented the appearances of recent, extensive, and violent peritonitis. The greater omentum was glued to the intestines beneath. A large quantity o sero-pus welled up from behind the uterus, which organ, as well as the liver, presented on its surface many patches of recent lymph. The uterine cavity contained some broken down clots of blood, and the external os was dark purple, and slightly ragged at one angle.

DR. FINNELL, in presenting the uterus of this woman to the Society, alluded at some length to its points of interest, whether viewed pathologically or medico-legally. But paramount over all was the existence of an abnormal canal, which starting from the cervix quite near the internal os, terminated very soon in a *cul de sac* in the uterine muscular wall. It was large enough to admit with ease the passage of the handle of a scalpel, and, in his opinion, was the result of an accident which had occurred to the gentleman in the introduction of the sound, notwithstanding the care and circumspection used.

DR. LYNCH doubted that a probe-pointed sound used in the careful and gentle manner described, could be made to penetrate the tissues of a uterus so healthy as this appeared to be.

DR. JOHN BEACH supposed the sound to have entered a sinus, from which slight force might push it into the uterine wall. He, however, doubted the relation of cause and effect between the wound and the peritonitis, as the uterine tissues presented no evidences of inflammation.

DR. CONNOLLY said it was a question whether this woman had not been tampered with by an abortionist previous to the regular physician's attendance, and agreed with the preceding speaker, that the relation between the wound and the peritonitis was not evident.

DR. WOOSTER BEACH said his experience at autopsies had taught him that inflammation might exist in a remote part of the peritoneum, and yet be due to injury of the uterus. He was not prepared to offer an explanation of this fact.

DR. STIRLING alluded to the woman's surroundings, which, taken in connection with the ragged condition of the external os uteri, led him to suppose that attempts had been made to induce a miscarriage, previous to the regular's attendance.

DR. NEWMAN closed the discussion by stating that the instrument used in this case was the uterine sound with a blunt end, about No. 7, catheter size. He called the attention of the Society to the fact that in the present contracted and shrivelled state of the parts the diameter of the wound is much larger than that of the sound. How much larger, then, it must have been in the fresh condition! He failed to discover any reasons for supposing it to have been made by a sound.

The meeting then adjourned.

N. Y. MEDICAL JOURNAL ASSOCIATION.

STATED REUNION, FRIDAY, NOVEMBER 29, 1867.

DR. GURDON BUCK, PRESIDENT, in the Chair.

PERIODICAL FEVERS.

DR. LEROY M. YALE read an elaborate resumé of the recent contributions to the literature of periodical fevers. Under their ætiology and pathology were given the views of Salisbury, with which our readers are doubtless familiar; of Robin, who attributes malarious fevers, as well as nearly all zymotic diseases, to the vitiation of the blood by a rapidly putrefactive, coagulable, albuminoid substance to be found in all miasmatic air (*Sur les Humeurs*, p. 195 et seq.); and of De Beaufort, who bases upon this theory a very ingenious pathology (*Bul-*

letin Générale de Thérapeutique, Sept. 30, 1867). Under prophylaxis and treatment, reference was made to the prophylactic power claimed for tobacco; to the new modes of administering quinia, hypodermically, iatroleptically, and by inhalation; and to new anti-periodics, among which chloroform stands preëminent in its power of bringing on reaction from pernicious congestions. M. Eulenberg's experiments upon the modus operandi of quinia were mentioned. He concludes, though the value of his results is questioned, that it directly destroys muscular irritability, and paralyzes first the reflex nervous centres of the cord, and later the cerebral ganglia.

The discussion which followed assumed a very practical character.

Dr. H. S. Hewitt stated that he had used quinia as a prophylactic in many hundred cases, and had come to regard it as almost infallible.

Dr. C. C. Lee fully endorsed this view. He referred to an instance in the late war, where a body of eight hundred and fifty men, not before exposed, were suddenly compelled to encamp in a malarious region; seven hundred of them were put under a prophylactic regimen of quinia, and of these but four or five were attacked by the fever; while of the one hundred and fifty not so treated, only twenty or thirty escaped it. It was observed in these cases that this agent was less efficient for the control of the disease, when once established, than for its prevention.

Dr. Austin Flint related a singular effect of large doses of quinia in a case of violent congestive intermittent, which he had seen last summer in consultation. During the paroxysm several doses of twenty to forty grains were given, at intervals of two hours, until upwards of one hundred grains had been taken with no evidence of cinchonism. When the amount of one hundred and thirty grains was reached, there suddenly occurred total blindness, but without tinnitus aurium or other of the usual signs of over action of the drug. The blindness passed off in a few hours, and the paroxysm, which had threatened to be fatal, was happily arrested.

Dr. White had treated a case in which ten grains of the sulphate produced convulsions, and the patient stated that he had been similarly affected before. The valerianate, in small doses, was substituted with good effect. Dr. W. had met with another instance of the kind. He said that the surgeons upon the Panama Railroad had given a long and faithful trial to the various substitutes for quinia, only to abandon them and return to the sulphate of this alkaloid as the best anti-periodic.

Dr. Garrish had been using, with encouraging results, the hyposulphite of soda (gr. x.–xx. ter in die) in four cases which had resisted quinine and arsenic.

NEW SPLINT FOR FRACTURE OF THE THIGH.

Dr. Hewit presented a new splint for fractures of the thigh. It is composed of metal; the side-pieces, which are firmly united by cross-bars, are hinged at the knee, and the thigh and leg portions are fixed at any desired angle by means of a simple screw appliance; extension is made from the foot by any of the usual methods (screw, elastic strap, or weight), counter-extension by a perinæal pad attached to the inner side of the splint, and by a pelvic band attached to the outer side; coapting pads, shaped to fit the thigh, are fixed at any point by screw clamps which play along fenestræ in the side-pieces. The thigh is to be left without bandaging. Dr. H. claims for this splint the merits of simplicity, lightness, and firmness; openness, giving free ventilation to the limb, and enabling the surgeon to detect at once any deviation of the fragments from the right line; and, as its most important feature, that it secures such perfect coäptation as to reduce to the minimum the force of extension and counter-extension required.

Annual Meeting, Tuesday, December 3, 1867.

Dr. Stephen Smith, Vice-President, in the Chair.

REPORTS.

The report of the Treasurer, Dr. S. T. Hubbard, showed the total receipts for the year to have been $1634.32; total expenses, $2010.28; but by offsetting the bills against the Association by the amount due it, there was left a nominal debt of $29.68. The Treasurer stated that the expense of furnishing the new rooms had made an extra draft upon the funds, during the past year, such as would not soon be required again; and that in his opinion the current regular assessments would be ample to meet all demands upon the treasury.

The Board of Direction reported the condition of the Association very flourishing. A reserved fund had been guaranteed, to meet any deficit in its finances, but there had been no occasion to draw upon it. The society was larger than the year before, numbering at present about 160 members. Four members had died during the year: Drs. S. P. White, C. E. Morgan, J. B. McEwen, and Robert Watts. The library was steadily increasing in value.

The Librarian, Dr. B. S. Thompson, reported that at the beginning of the year the list of medical periodicals regularly taken embraced thirteen American, eight English, twelve German, and ten French journals. During the year eight journals had been added, making the number now received fifty-one. Donations had been received of one hundred and twenty-eight copies of transactions, monographs, journals, etc.; also of several photographs and engravings.

OFFICERS ELECT.

The Association proceeded to ballot for officers for the year. Dr. Stephen Smith declined to be a candidate for reëlection as Vice-President, from inability to be regularly present at the meetings, and Dr. Hubbard declined further service as Treasurer. With these exceptions the old Board was reëlected. The following are the officers chosen: President, Dr. Gurdon Buck; First Vice-President, Dr. Isaac E. Taylor; Second Vice-President, Dr. Samuel T. Hubbard; Recording Secretary, Dr. F. A. Burrall; Corresponding Secretary, Dr. Emil Noeggerath; Treasurer, Dr. H. P. Farnham; Trustees, to serve three years, Drs. F. H. Hamilton, F. J. Bumstead, Austin Flint, Sen., Alfred Underhill, and A. B. Mott.

EAST RIVER MEDICAL ASSOCIATION.

Stated Meeting, Nov. 5th, 1867.

Dr. V. Morse, President, in the Chair.

A CASE OF TWIN-DELIVERY, WITH INTERVAL OF SIXTEEN HOURS.

Dr. O'Sullivan read the history of an interesting case of twin-delivery, which occurred in his own practice; in which there had been an interval of sixteen hours between the birth of the first and second child. The point of interest was that after the birth of the first child, the uterus remained perfectly inactive. Hour after hour passed away, until at last it was determined to wait no longer. Fearing to give ergot, lest the presentation should prove to be an abnormal one, Dr. O'Sullivan thought seriously of delivery by version.

On introducing the hand into the vagina, for the purpose of making a thorough exploration, he found the pelvis ample—the head of the fœtus rather large, but not too much so for the lateral diameters, and presenting in the left occipito-iliac-posterior position.

The membranes were ruptured, when a few feeble pains followed, but soon ceased. Ergot was then given in the ordinary manner, with the desired result; the pains, from having been at first moderate, soon became satisfactorily powerful. The head readily engaged, the occiput rotating posteriorly, and passing though the hollow of the sacrum, and a male child of large size, strong and healthy, was delivered. The placenta was readily detached without any hæmorrhage. The patient made a good getting up. The interesting point in this case was in reference mainly to the long interval of time which had elapsed before the birth of the second child, it being, with some rare exceptions, probably the longest on record, in which the result to both mother and child was so favorable. It is probable that the propriety of non-interference in this case, until the uterus resumed its action, may be open to criticism, notwithstanding that no untoward symptoms of any kind ensued during the interval. With now nearly ten years additional experience in obstetric practice, and considerable in the use of the forceps, he would not now delay so long before attempting delivery; he would not wait at furthest until a single hour had elapsed. If it were a vertex presentation, and had engaged sufficiently, he would use the forceps; if this were not feasible, he should then turn and deliver. Either of the above expedients he deemed preferable to the use of ergot. There is, however, very respectable authority for postponing interference in these cases unless compelled to the contrary by accidental circumstances, such as convulsions, hæmorrhage, etc. There are several instances on record, though of course very rare, when the second child has been retained for days and even weeks.

Dr. Abbott asked why the doctor preferred using forceps in such cases to administering ergot. This question gave rise to an animated discussion, which continued until a late hour, when it was finally resolved to make "Parturients" the subject for debate at the next meeting.

Correspondence.

MEDICAL MATTERS IN PARIS.

(FROM OUR SPECIAL CORRESPONDENT.)

To the Editor of the Medical Record.

CURIOUS NERVOUS PHENOMENA.

Sir—The "sensation" of the week centres around the discussion of a remarkable circumstance occurring in the wards of M. Richet at Hotel Dieu. On the 23d of October, a woman entered the service, who, falling against some pieces of sheet copper, had been wounded in the forearm by their sharp edge, in such a manner that the radial artery and median nerve had been completely divided. Notwithstanding this section, sensibility remained in the thumb, index and middle fingers, and the external border of the ring finger, all furnished by the median nerve; moreover, the peripheric extremity of this nerve was exquisitely sensitive to the touch of the pincers.

The fact has been examined and acknowledged by a number of distinguished physicians. There can be no doubt that the median was completely severed. But it is difficult to explain a phenomenon so contrary to the facts which form the basis of current physiological theories, according to which the peripheric extremity of a severed motor nerve preserves its motor power, and that of a sensitive nerve loses its sensibility. Dr Fort, in the Union Médicale, endeavors to prove that the case is one of *recurrent* sensibility, like that described by Bernard as existing in the facial nerve. Irritation of this nerve excites pain, on account of its anastomoses with the trigeminus. In the same way, says Dr. Fort, we must infer from this fact itself that the radial and cubital nerves furnish anastomoses with the median, by which this latter is enabled to preserve its sensibility even after section.

This argument s rather *post factum*. Moreover, as observed by Dr. Reveillant in the *Gazette des Hôpitaux*, there is no analogy between the coupling of a sensitive and motor nerve in a single "nervous pair" (as in the case of the 5th and the 7th) and this supposed anastomosis between two sensitive nerves, which is justified by no precedent whatever. Dr. Reveillant maintains, that since the grand palmar nerve is more deeply situated than the median at the wrist on the level of the wound, since it is united to the median only by a loose cellular tissue which permits great mobility, since the median was torn, instead of being distinctly cut, and the wound was deepest on the radial border of the wrist—in view of these considerations it is probable that the great palmar nerve was not divided, as at first supposed, and the recurrent sensibility was due to its presence in the parts furnished by the median. But this explanation, though hypothetically satisfactory for the sensibility remaining in the hand, renders no account of that preserved in the peripheric extremity of the median, since the palmar branch is given off from this latter nerve at a point above the situation of the wound, and afterward has no connection with the median. Dr. Richet has not yet spoken. His detailed description of the case is presently expected, and may throw light on this vexed question.

EXPERIMENTS UPON CRIMINALS.

At the naval medical school of Brest, M. le professeur Duval has pursued some physiological researches in a direction that continually tends to become restricted. If the humanitarian tendencies of the age prevail, capital punishment will be abolished, and physiologists for ever deprived of the bodies of criminals as material for experiments. In view of this unfortunate contingency, all experiments actually performed are invested with a double interest, on account of the possibility that they may be the last permitted in civilized countries.

The following is a *résumé* of the results obtained by M. Duval, in galvanization of the different apparatus of the bodies of criminals, within five or six minutes after their execution.

Nervous System.—Galvanization of the motor ocular nerve, at its point of immersion in the cavernous sinus, caused instant contraction of the dilated pupil. In two subjects reflex movements were excited by a brusque tap on the hands or feet. The contractions of the deltoid, brachial, biceps, anterior tibial and gastro-nervous muscles were especially evident. In the case of a slight irritation of the surface, exciting contraction of the subjacent muscles, the action was evidently reflex: where a smart percussion had been practised, M. Duval supposes that the muscular fibre had been directly excited, independent of the nerves. This experiment confirms Schiff's refutation of the theory that warm-blooded animals could not exhibit reflex movements after decapitation.

Digestive Apparatus.—The stomach and small intestines

continued to exhibit peristaltic movements for several minutes. The stomach was filled with food, and in the midst of digestion, but none of its contents escaped at the orifices after removal of the organ from the abdomen, so efficient was the contraction of the sphincters. A remarkable prominence of the solitary closed follicles of the ilium was observed. This fact is interesting, on account of a theory recently proposed, which considers such prominence to be a characteristic lesion of cholera.

Circulatory Apparatus.—The primitive carotids were divided, and their extremities were seen to rise at regular intervals, elongate beyond the level of the wound, and then subside; at each impulse a small quantity of frothy vermilion blood escaped.

On the same two subjects, the thorax was opened seven minutes after death, and the heart found to be beating within the pericardium. Upon incision of this membrane, the following succession of phenomena was observed. At the beginning of each movement the auricular appendix was suddenly raised, and distanced from the aorta, then fell as abruptly into its primitive position. In rising, the appendix lengthened, and the indentures of the circumferencese parated like the fingers of an outstretched hand. At the same time with this erection of the appendix, occurred an *expansion* of the auricle, as if it were distended by an efflux of liquid. The contraction of the ventricules followed that of the auricles in less than the fifth of a second. These cavities were shortened in all their diameters, their surface became furrowed, they contracted together in perfect synchronism.

After cessation of the spontaneous beatings of the heart, the movements were renewed by the application of galvanism, first to the organ itself, afterward to the spinal cord.

M. Duval found that a moderate degree of contractility existed in the walls of the aorta, which, irritated by the insertion of a finger, were found to slightly press upon it.

Respiratory Apparatus.—Upon galvanization of the external or internal intercostal muscles, or of both together, the under rib was raised and pushed outward. M. Duval concludes that both these muscles, concerning which, from the time of Haller and Hamberger, there has been so much discussion, are inspiratory. M. Duchenne (de Boulogne) impresses this fact into his service to prove the same theory.

ATROPHY OF MUSCLES OF TRUNK AND LIMBS.

I am not sure whether I have mentioned the lecture delivered by Duchenne upon a patient in the wards of M. Bouillaud, affected with atrophy of nearly all the external muscles of the trunk and limbs. The intercostal muscles were entirely wasted, and the chest is flattened in a remarkable manner. The respiration is performed by the diaphragm. M. Duchenne remarked, that since the thorax contracted, as in expiration, as soon as the intercostal muscles became powerless, it was just to infer that in health they antagonized this contraction; that is, opposed the action of the expiratory muscles. It seems to me evident, however, that the case in question proved that they exerted such antagonism in virtue of their *tonicity*, not at all on account of the intermittent contraction during inspiration. The experiments of M. Duval are no more conclusive, for although a muscular fibre when galvanized should elevate a rib to which its fibres were attached, we are not thence to infer that it contracts habitually during life, or therefore that it directly elevates the ribs during inspiration.

P. C. M.

CONTRACTIONS OF THE MUSCULAR COATS OF THE STOMACH IN VOMITING.

To the Editor of the Medical Record.

Sir—In a recent review (Medical Record, *Dec.* 2, 1867) of *the "Physiology of Man," vol. ii.*, by Austin Flint, Jr., M.D., "we learn," says the writer, "that the diaphragm is the principal agent in vomiting, that this muscle is aided by the abdominal muscles, *the muscular coats of the stomach being at the time relaxed.*"

We present the following facts, not only as a contribution to physiological science, but as our reasons for differing largely from the views entertained by the distinguished author on the subject in question.

On the 23d of April, 1858, at Lock, Berlin, Wayne Co., New York, while performing the operation of ovariotomy, which proved successful, the incision extending from the ensiform cartilage to the pubes, and after the removal of two large tumors weighing nearly forty pounds, my patient began to vomit.

Desiring to settle for myself the physiological question whether the muscular coats of the stomach are mechanical agents in vomiting, I introduced my hand into the abdomen, and placed it upon the stomach. That organ *felt and acted like a living thing, its coats were not relaxed, but contracted under my hand* at each of three consecutive retchings, during which a large quantity of food was ejected. The frequency of gastrotomy renders it probable that other observers may confirm my experience, and we may thus establish a fact of value to science and of interest to scientific men.

Very respectfully,
Your obedient servant,
Hazard C. Potter, M.D.

Geneva, December, 1867.

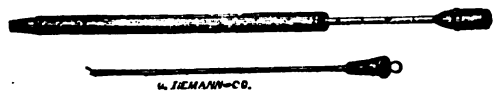
New Instruments.

A POCKET-CASE HYPODERMIC SYRINGE.

By D. M. STIMSON, M.D.

The accompanying cut represents a convenient form of hypodermic syringe to be carried in the pocket-case.

The idea which is here carried out was suggested to me two years ago by Dr. G. H. Wynkoop, of this city.



The point, inclosing the wire cleaner, fits into a hollow graduated piston. The barrel is an ordinary silver tube, the size of a No. 10 catheter, and is about three inches long.

New Publications.

Books and Pamphlets received.

A Practical Treatise on Diseases of Children. By D. Francis Condie, M.D., Fellow of the College of Physicians, etc. 6th Edition. Revised and enlarged. Philadelphia: H. C. Lea. 1868.

Observations on the Nature and Treatment of Polypus of the Ear. By Edward E. Clarke, M.D., Professor of Materia Medica in Howard University, etc., etc. Pp. 71.

42nd Annual Report of the Mass. Charitable Eye and Ear Infirmary. For the Year ending Sept. 30th, 1867. Boston. 1867.

On the Signs and Diseases of Pregnancy. By Thomas Hawkes Tanner, M.D., F.L.S., etc. From Second and Enlarged London Edition. Philadelphia, H. C. Lea. 1868.

Medical Items and News.

Dr. Livingstone probably Alive.—Letters received in London give assurance of the safety of Dr. Livingstone, the African explorer, who was reported to have been killed by the natives. In April last he was in good health and continuing his explorations.

Eulogy on Prof. Valentine Mott.—Prof. Samuel D. Gross, of Philadelphia, Pa., pronounced a Eulogy on the Life and Character of the late Prof. Valentine Mott, at the Bellevue Hospital Medical College, Dec. 14, 1867. The travels of the eminent deceased, his intercourse with the distinguished medical and surgical savants in Europe, as well as other incidents in his eventful career, were fully discussed.

Dr. Vernois, Physician of the Hotel Dieu, has resigned his position.

Dr. Barrey.—We regret to announce the death of Dr. Barrey, Medical Director of the Insane Asylum at Rodez. He died on the 1st of October, after a short and painful illness, in the 51st year of his age.

Suicide of a Distinguished Surgeon.—Dr. Ludwig Lewinsky, head of one of the surgical divisions of the General Hospital at Vienna, was found dead in his quarters, on the 17th of October. A farewell letter, addressed to his wife, leaves no doubt of his death being the result of his own deliberate action. He had been for some months haunted with the fear of becoming insane, a fear which received some substantial basis in the fact of his being afflicted, during this period, with occasional fits of *insomnia*.

An autopsy, conducted by the celebrated Rokitansky, discovered unquestionable evidences of poisoning by cyanide of potassium. There was also found an abnormal thickening of the membranes of the brain, sufficient to account for the sleeplessness referred to, which in the end had led to so melancholy a result.

Trichinasis and its effects upon an Unbeliever.—At a recent public meeting, while Professor Virchow was urging upon the audience the necessity of microscopical examinations of all meats supposed to be infected with trichina, a distinguished veterinarian arose and astonished every one present with the announcement that the existence of trichinasis was an unfounded illusion. Considerable sensation was of course produced in consequence, when one of the gentlemen present challenged the horse-doctor to eat a portion of the meat which was said to contain those creatures. The challenge was caught up by the assemblage, and amid the greatest enthusiasm, the valiant opposer of science was forced to partake, immediately after which he left the room. A few days after the veterinarian was helplessly paralyzed in his bed, and was willing to acknowledge his error.

Surgical Instruments from Pompeii.—M. Scoutettin has, by permission of the Italian Government, obtained photographic representations of the different surgical instruments found at Herculaneum and at Pompeii. There are more than three hundred of these instruments, but only about sixty of dissimilar kinds. Among the most interesting are some brass catheters, similar to those described by Galen, the curves of which are better than many of the sounds and catheters made at the present day, and a probe presented by Galen to a magistrate named Erastitrate, and which seems preferable, in a practical point of view, to those now in use.

Medical Statistics of the U. S. Navy.—From the report of the Hon. Gideon Welles, Secretary of the Navy (Dec. 2. 1867), we extract the following:

The Chief of the Bureau of Medicine and Surgery presents not only the usual report of sickness and death in the navy during the year, but gives in addition interesting tables showing the number of sick of each squadron engaged on the blockade during the war, together with the total of each disease treated, number of deaths on the blockade during the rebellion, proportion of deaths to the number of cases treated, and the proportion of deaths to the number of ship's company. The summary shows that from the commencement of the rebellion to the 30th of June, 1865, there were under treatment 114,038 cases; that there were 2,532 deaths, the proportion of deaths to the number of cases treated being ·0175. At the close of the year 1865 there remained under treatment 853 cases; during the year 1866 there occurred 24,350 cases of disease, injury, etc., making a total of 25,203 cases treated during the year, of which 310 died; 23,954 were returned to duty or discharged the service, leaving 939 cases under treatment at the end of the year 1866. The proportion of cases admitted to the whole number of persons in the service was about 1·46, or each person was on the sick list $1\frac{1}{46}$ times during the year. The proportion of deaths to the whole number in service was ·018; and the percentage of deaths to the whole number of cases treated is ·012, or less than two per cent., taking the average strength of the navy—officers, seamen, marines, engineer service and coast survey included—for the year 1866, to be 17,193. The total number of deaths from all causes, reported at the Navy Department from October 1, 1866, to September 30, 1867, is 395. The number of insane of the navy under treatment in the government asylum near Washington, during the year ending 30th September, 1867, was 24; number now under treatment, 18. The necessity for enlarging the laboratory accommodation continues to press itself upon the attention of the bureau, and estimates for this purpose have again been submitted.

Dr. Dixi Crosby, LL.D., who succeeded the late Dr. Mussey in the professorship of surgery in the Dartmouth Medical School in 1838, proposes to retire from active connection with the school this year. He will then have completed his thirtieth course of lectures. Dr. Crosby is the only member of the medical faculty of 1838 now retaining position in the institution. Dr. Oliver W. Holmes was then professor of anatomy and physiology, and the Hon. Joel Parker, LL.D., of medical jurisprudence.

M. Gosselin, Professor of Clinical Surgery (at La Pitié), has been appointed Professor of Clinical Surgery in La Charité.

New Hospital.—The city of Rochester, in this State, has a new hospital which is evidently a credit to the country. It is complete in all its arrangements, as we judge from the account of it in "*The Hospital Review*, a journal devoted to the interests of the sick and suffering at the Rochester City Hospital." There is a surgical, medical, lying-in, and eye and ear department; attending physicians, H. W. Dean, M.D., U. U. Ely, M.D., David Little, M.D.; surgeons, H. F. Montgomary, M.D., H. H. Langworthy, M.D., John F. Whitbeck, M.D.; ophthalmic and aural surgeon, Charles E. Rider, M.D.

Population of France.—At the close of a late discussion in the French Academy, on the growth of the population, it seems conceded that while the population is increasing sensibly, the rate is gradually diminishing.

New Orleans an Infected Port.—A recent proclamation of the Metropolitan Board of Health has made New Orleans "an infected place within the meaning of the Health Laws of this place." Appropriate quaran-

tine regulations are enjoined in respect to persons and vessels coming from thence, cholera still existing there, which are to continue in force until the 21st day of February of the ensuing year, at noon.

THE QUESTION OF RANK.—The chiefs of the Bureaux of Medicine and Surgery, of Provisions and Clothing, and of Steam Engineering, bring to the notice of the department the claims of their respective corps to increased rank. It is urged that by the recent creation of the several grades of admiral, of commodore, and lieutenant commander, the rank of the staff corps has, in effect, been reduced. The law now provides for the appointment of fleet surgeons, fleet paymasters, and fleet engineers, but the rank is only temporary, ceasing when the officer is detached from fleet duty. If these grades were made permanent and to embrace a sufficient number for the service required of the officers standing at the head of their respective lists, and the rank now temporarily given to fleet officers and to the other grades legalized, it is thought that the staff corps would be generally satisfied. It is understood that they propose to bring the matter of increased rank to the notice of Congress, and such legislation as may seem equitable and just is recommended.

PREVENTING RAILROAD COLLISIONS.—A correspondent of the *Mechanics' Magazine* proposes a plan whereby every train on a track shall communicate with another, before or behind it, whenever the two approach within a certain distance. Electricity is the means employed, the engines of the trains carrying batteries one wire from which connects with the engine bell, the other connecting with the earth. Light insulated supplemental rails, made in continuous length of two miles each, are laid by the side of the main rail, so that the tire of the locomotive wheel runs on both. As long as two trains are not at the same time on one length of conducting rail, no electric current can pass on account of the break joint, but as soon as they come within this particular distance of each other the circuit is completed and both bells will ring.—*Scientific American.*

N. Y. MEDICAL JOURNAL ASSOCIATION.—The weekly Friday evening reunions of this Association were resumed on the 8th of November. They are fully attended, and are occasions of no little scientific and social interest. At each meeting is presented a resumé of the current literature of some special subject, prepared from the ample resources on the Society's shelves, by a member previously appointed. Original papers are frequently read, and new instruments or other matters of professional interest brought to the notice of the meeting. After discussion of the subjects presented, the Society adjourns to coffee and sandwiches, and the remainder of the evening is devoted to social converse. We shall furnish our readers reports of such papers and discussions as may be of special interest.

BLOOD IN THE BODY.—The amount of blood in an adult is nearly thirty pounds, or full one-fifth of the entire weight. The heart is six inches in length and four inches in diameter, and beats seventy times per minute, 4,200 times per hour, 100,800 times per day, 36,772,000 times per year, 2,565,440,000 in three-score and ten, and at each beat two and a half ounces of blood are thrown out of it, one hundred and seventy-five ounces per minute, six hundred and fifty-six pounds per hour, seven hundred and three-fourth tons per day. All the blood in the body passes through the heart every three minutes.—*St. Louis Medical Reporter.*

TOBACCO AND PICKLES.—If Englishmen have had exaggerated ideas about the tendency towards rotundity exhibited by all Dutchmen, they have by no means overrated the national habit of smoking. The Dutchman of to-day is as great a smoker as was his great-great-grandfather. The pipe has, however, given way to the cigar; and the meanest laborer indulges himself, often when at work, with the "weed" which costs him less than a farthing. Passengers on railways smoke as a matter of course; and the guard, as he passes from carriage to carriage to examine the tickets, does not hesitate to rest now and again in one of the carriages to smoke a cigar with any neighbor or acquaintance. The teeth of a Dutchman are nearly as characteristic as the skin of an Englishman who has lived for a long time in India; they are much discolored, and many of the incisors are carious. The Odontological Society will find the best specimens of discolored teeth from smoking among modern Dutchmen. The Dutchman's partiality for pickles is peculiar, yet easily explained. In Rotterdam, but more largely in Amsterdam, pickle-stalls are not much less frequent than apple-stalls in London. The pickle-stall seems to be, with many workmen, the half-way house between the workshop and the dining-room. This nation of confirmed smokers abounds in dyspeptics; and the poorer classes give their clammed palates a fillip occasionally with the sour and acid substances sold in the streets.—*British Med. Jour.*

WEIGHT OF THE HUMAN BRAIN.—In the *Archiv für Anthropologie*, Dr. A. WEISBACK has been giving several articles on the relative weight of the brains of the populations of the Austrian empire, in respect to the bodily size, age, sex, and diseases. Some of his conclusions are as follows: "Among Germans twenty years of age, those of medium height have the largest brains. With increasing size the cerebellum increases, while the cerebrum relatively decreases. In chronic sickness the total weight of the brain decreases, but the decrease is confined to the cerebrum and the pons, the cerebellum relatively increasing. The total weight of the brain, and the actual weight of the cerebrum, are greatest at about the age of thirty, from which period both steadily decrease until, at the age of eighty, ten per cent. is lost. The pons varolii increases to the fiftieth year, and then steadily decreases, sometimes seventeen per cent. in a decade. On the whole the female brain is smaller than the male, but in certain races this difference is confined to the posterior, in others to the anterior segment."

OUR BLACK DESCENDANTS.—At a meeting of anthropologists, which had also an international character, at Paris lately, M. Quatrefages, one of the most eminent French *savans*, raised the question whether the first inhabitants of Europe were white or black. M. Quatrefages thinks that the whites preceded everywhere the negroes, who descend from them. The principal argument which he invokes in favor of that opinion is the following. All travellers who have lived in countries where only the negro race dwelt have remarked that sometimes children were born of paler color, less distant from the white type. This, says M. Quatrefages, is to be explained by the influence of white ancestors, whose type reappears exceptionally amongst their negro descendants. This reappearance of the ancestral type is what is called atavism; "and, as black children are never found amongst the white races, it must be inferred that, if the negroes descend from the whites, the whites do not descend from the negroes."—*British Medical Journal.*

Original Communications.

EXTIRPATION OF A UTERINE TUMOR.

By G. P. HACKENBERG, M.D.,

HUDSON, N. Y.

About a year ago, I presented to the New York Pathological Society a large abdominal tumor I removed from a Southern lady, then residing in the city of New York. The tumor had been diagnosticated as ovarian, but after its removal it was ascertained that it was uterine. As a similar case has occurred in the practice of Dr. E. Krackowizer, recently published in the MEDICAL RECORD, I have thought that a history of the case under my management might not only prove interesting, but perhaps tend to put us more on our guard in making out the diagnosis of abdominal tumors.

The patient I operated upon was forty-five years of age. She was a maiden lady, and always enjoyed a good degree of general health; never was troubled with any menstrual irregularities, and never suffered much from immediate uterine disturbances, or even through their sympathetic influences. Three years previous to the time of the operation, her general health, from unknown causes, received a shock, from which she never fairly rallied. She, however, continued to perform the duties of her vocation, which was that of teaching. About a year later she detected an abdominal enlargement, which gradually increased until it had assumed an enormous size. The enlargement at first occasioned no special inconvenience, but as the tumor increased in size, exhaustion and dyspnœa set in, and the patient became extremely anxious for surgical aid. She was a lady of rare intelligence, and expressed a positiveness that the tumor originated within the left ovarian region.

My first examination was about a month before the operation, having only seen her twice during that time, and she then informed me that she had been examined by Professor Eve, and other surgeons of the South, and that they had diagnosed her case ovarian tumor, and recommended an operation. On account of the increase of dyspnœa as the tumor enlarged, the patient was extremely anxious for an operation, and for that purpose came to New York. Owing to the positiveness of the patient, and the case being diagnosed by some of the most distinguished surgeons of the South, I must confess I was not strictly critical in making out a distinct and unbiassed diagnosis of my own; however, I doubted the serous character of the enlargement. I saw her again on the day of the operation, and she was again examined by Dr. T. H. Hammond, now of St. Louis, and Drs. John Beach, Hyslop, Wohlforth, and others from the city of New York. They likewise considered the case ovarian tumor, and saw no objection to an operation. The tumor was of an enormous size, and weighing probably, in situ, not less than twenty-five pounds, and occupied almost the entire pelvic cavity, and anterior part of the abdomen. To the touch it was smooth and elastic, and painless even by rude manipulations. It appeared to be movable to a limited degree. On making an examination, as it was expected, the tumor had forced itself into the cul-de-sac of the vagina, crowding the uterus against the sacrum. The os was under the manipulating control of the index finger, and was overhung by the broad base of the tumor.

The uterine sound was not resorted to, in making out our diagnosis, for the following reasons: 1st. The patient had determined upon running the risk of an operation, and objected to the use of the sound. 2d. We did not deem the use of the instrument absolutely necessary, as the removal of the tumor became imperative, regardless of its character, whether uterine or ovarian. 3d. Owing to its large size, its great pressure on the uterus, its supposed long pedicle, we did not think that the sound would serve us to make out a clear case.

Our omission in using this valuable instrument, therefore, gives us not much regret. Even in the hands of such skilful and experienced surgeons as Krackowizer and Kammerer it has deceived them in rendering a correct diagnosis in their case of uterine tumor.

After the patient had taken the risk of the operation fully into consideration, and still decided in its favor, we carefully prepared her for it. Before she was taken to the operating table, an ounce of brandy was given. As she lay down to receive the chloroform she felt somewhat the influence of the spirits. As soon as she was under the influence of the anæsthetic an incision was made to the extent of about six inches, between the umbilicus and symphysis pubis. With rapid dissection the tumor was exposed.

I must state that at the examination of the tumor I was not positive, as were my assistants, that we had fluctuation, and expressed the idea that we might be deceived by the superabundance of adipose tissue connected with the walls of the abdomen. In my own mind the differential diagnosis of the case was between a fibrous uterine and fibrous ovarian tumor; declining, however, to favor the latter. Even if uterine, I considered the operation not necessarily fatal, and therefore not contra-indicated. Dr. J. D. B. Stillman, member of the New York Pathological Society, published in the New York Journal of Medicine Dr. Herff's case of fibrous tumor of the uterus, which he successfully removed by abdominal section. The case had been diagnosed ovarian tumor. The patient permanently recovered. Dr. Atlee, of Philadelphia, performed the operation twice with success.

After the tumor was exposed, it was found that the omentum was adherent over part of its upper anterior surface. These adhesions were gently broken away. Such was the size of the tumor and consequently the pressure from within, that it was impossible to make out the relation the pedicle held with the uterus or the ovaries. A trocar was thrust into the tumor, and instead of serum presenting itself through the canula, we had venous blood, with a tendency to flow freely. I therefore quickly removed the trocar and firmly plugged up the bleeding orifice with lint, and checked the hæmorrhage. A solid tumor had now revealed itself. On the surface, it was freely supplied with veins; many of them were large and well distended. The crisis of the operation was now presented, and for a moment was critical in the extreme. The question was not whether to desist, for the size of the tumor, the great pressure from within, on a now tense gaping wound, made it impossible. Therefore I quickly extended the abdominal section upward, within a few inches of the ensiform cartilage; so as to enable me to dislodge it from its bed. The extirpation was then only accomplished by hunting out the smallest end of the mass, and bringing it out first; so as to have the body of the tumor to follow like a wedge. As the growth was supported by two assistants, I carried the chain of the écraseur around the pedicle, and proceeded quickly to make a deep indentation into it, for the purpose of applying a strong ligature. I say this was done quickly, in order to economize blood by cutting short instantaneously the circulation of the tumor. After the ligature was thus applied, the chain of the écraseur was

carried toward its base, and promptly removed. No hæmorrhage followed. The operation was performed in thirty minutes.

After the wound was carefully cleansed, and all oozing of blood discontinued, we closed it by silver sutures, one of them holding the extreme end of the stump.

As the patient emerged from the influence of chloroform the sutures were introduced. Brandy and half a grain of acetate of morphine were administered after the operation; and the patient gradually passed into a favorable reaction. The operation was performed at 11 o'clock, A.M., and when I saw her in the evening she was in a tolerably comfortable condition; the next day symptoms of peritonitis set in, accompanied with constitutional depression. With the abdominal soreness, the pulse was small and very quick; the tongue dry and coated with fresh sordes. She was remarkably quiet. There was considerable serous oozing from the wound; but not much blood. The symptoms of peritonitis increased in spite of the remedies we brought to bear against them, until the morning of the third day, when the extreme depression terminated in death. No post-mortem examination was permitted.

In examining further into some of the symptoms of this remarkable case, it appears to me now that we can trace in a measure their true character.

That the menstrual function was not impaired was quite significant, if not pathognomonic in the case. Ovaries being free of disease, with good systemic blood, usually perform their function uninterruptedly; but where one or both are diseased they show menstrual trouble. Even where but one is affected, the other through sympathy refuses to perform its office; and their disease always manifests manifold sympathetic troubles. Uterine degeneration, partly under revulsive influences, but more owing to a deterioration of the blood, will likewise suspend the healthy action of the ovaries; but no ex-uterine growth will have the same effect, as long as the blood is left with its normal standard of fibre. Therefore the insidious manner in which the disease developed itself, and the little disturbance it caused to the general system, even after the tumor had grown to a considerable size, should have excited our suspicion, that the disease was neither ovarian nor a malignant degeneration of the uterus. In either case the symptoms would have been more ative.

The tumor was movable, or rather floating, as uterine tumors usually are. In Dr. Krackowizer's case the mobility of the tumor was in such a degree, that in the examination of the case there was no agreement from which side it originated. This feature alone should awaken suspicion that the tumor was of central origin.

As a means to make out our diagnosis in this disease, the use of the uterine sound is not to be neglected; but without corroborating symptoms to sustain us, what in our hands it might reveal should be received with a cautious consideration.

The examination, per rectum, is of the greatest importance, as the relative position of morbid growth, within the base of the pelvic cavity, with the uterine organs can be accurately ascertained.

In uterine tumors, the developing symptoms are peculiar. They are the play of physiology more than pathology; being somewhat akin to those of gestation. They manifest themselves not only by characteristic sensations, but leave more or less a print on the os, tincæ, the mammary gland, the stomach, and the urinary secretions. In uterine tumor the mammary glands are well developed; in ovarian tumor the tendency is to atrophy of these organs.

In uterine tumor there is not the tendency of the body to waste, and the development of cachexia that there is in ovarian tumors and malignant degeneration of the uterus. Some time after the first stages of the disease have passed over, for a period of several months, there is a tendency to obesity. This was the case with my patient.

In the advanced stage of the disease, the pain is likewise characteristic. It is like bearing a heavy weight, paroxysmally manifesting itself in catching, quickening sensations. It is like an ill-defined quickening sensation, common in gestation. The pain in the back is likewise more troublesome in this disease than in ovarian tumor.

In uterine tumor the uterus is more or less in an unusually developed state, with its sensibility exalted. Therefore in menstruation there is more or less either dysmenorrhœa or menorrhagia, if not both. This is not owing to any morbid condition of the ovaries, but simply to the increased sensibility of the uterus, and may be so slight as even to pass the special notice of the patient, her mind being so intently occupied with the main disease. The developed condition of the uterus can but be detected by way of the rectum.

Although dyspnœa may be considerable in all excessive growths of abdominal tumors, in ovarian tumors this symptom is particularly troublesome. There is even a marked difference in this symptom between fibrous and serous tumors of the same kind, the latter causing more difficult respiration than the former. These differences are owing to the more rapid enlargement taking place in the liquid tumors than those that are solid. And paroxysmal dyspnœa may be accounted for, by the sudden changes in the pressure on the diaphragm, caused either by gaseous or fæcal accumulations within certain portions of the alimentary canal.

THE PATHOLOGY OF THE URINARY ORGANS AND OF THEIR SECRETION.

BEING A REPORT READ BEFORE THE

NEW YORK MEDICAL JOURNAL ASSOCIATION, DEC. 13, 1867.

By W. B. LEWIS, M.D.

The first department of our extensive subject is illustrated by a number of cases collected from various sources. After these are presented such recent observations, as were deemed of interest or importance, upon the symptoms and treatment of those diseases of which a morbid condition of the urine is pathognomonic; then upon some newly discovered peculiarities of that fluid in general diseases; and, finally, upon certain urinary sediments and the source of urea.

In Beale's Archives for April of this year is mentioned a case of phthisis, in which a fungus was found in the pelvis of the left kidney, nearly filling it with a white pultaceous mass adherent to the apices of many of the pyramids. On detaching this, a ragged and somewhat softened surface of a yellowish-white color was left. The substance of the pyramid for a varying depth, averaging ⅛ of an inch, was of the same whitish color, contrasting strongly with the dark crimson of the congested tissue around. The diseased portions were firm, except at the top, and much resembled tubercle. Two or three of the pyramids of the right kidney were similarly affected to a less extent. The rest of the organs appeared healthy.

The pulpy matter proved to consist of the sporules and mycelium of a microscopic fungus, apparently a species of oïdium, which is fully described and figured. It resembles the penicilium glaucum in outline. There

was no sugar in the urine three days before death, and no history of diabetes; no signs of a similar growth were found elsewhere in the body; hence it is inferred that the fungus had crept up the urinary tract from aphthous patches which may have existed about the orifice of the urethra, or from some parasite of the skin.

Dr. Fleming exhibited to the Dublin Pathological Society specimens illustrative of primary cancer of the kidneys, and a cancerous tumor of the prostate. The patient, sixty years of age, had long been laboring under urinary disease which had resulted in incontinence, attended with occasional paroxysms of pain. There was a larger amount of fever than is usual, great thirst, unsteady pulse, and irregular bowels, without tenesmus. Had never had hæmaturia. A small amount of urine collected was acid and clear. There was no abdominal tumor, and no stone. There was a slight obstruction to the entrance of a sound, in the prostate, giving the sensation of a nodulated hardness.

Death occurred in a fortnight. Before death the incontinence became retention, and at the autopsy the bladder was distended with urine. The kidneys were greatly enlarged, adherent to the surrounding parts, and containing, upon the surface, and throughout their substance, numerous morbid deposits of a whitish-yellow color, of various sizes. The prostate was large, very hard, and nodulated. Section showed an isolated tumor, apparently cystic.

The specimens were instructive to the surgeon, as showing that symptoms in many diseases of these organs were treacherous: that all the suffering will be referred in some cases to the bladder, while in others all the distinctive symptoms will be referred to the region of the kidneys, and yet vesical calculus alone may be found to occasion local lesions.

Dr. Cheever reports two cases of supposed perinephritic abscess, which occurred in the Boston City Hospital. One, an anæmic girl of seventeen, in whom the menses had never appeared, had suffered for three years from incontinence of urine, but was otherwise moderately healthy. She had a fluctuating swelling, three inches in diameter, in the right lumbar region, without redness, and but little tender. This had been two weeks in appearing. No weakness of legs, no evidence of hip disease, no chills, but profuse sweats within the fortnight. The tumor was opened, giving exit to a considerable quantity of laudable pus, free from odor. A probe passed in three inches perpendicularly. No denuded bone felt; probe strikes an elastic wall. Nothing abnormal in the urine. Discharged, nearly well, in a month.

The other patient, an Irish domestic, age seventeen, was of healthy parents. Four weeks before admission, after wetting her feet, the menstrual flow ceased, and she had trouble in micturition, which at length resulted in complete incontinence. No dribbling, however, while recumbent. During night, passed water five or six times, owing to pain at meatus. Pulse 90, temperature 100°, bowels costive, tenderness in right lumbar region. Urine orange, acid, 1017, largely albuminous. A large amount of pus, but no casts or blood. She now began to have slight chills, followed by pyrexia, and in two months had fixed pain in right lumbar region. A troublesome cough set in. At the end of five months deep fluctuation being felt, a trochar was introduced, and about two ounces of thick, fœtid pus discharged; that last appearing was curd-like. A probe entered three inches, reaching a soft, elastic wall. No bone felt anywhere; no evidence of spinal disease or hip trouble. Shortly afterwards there was more pus in the urine, but less pain. Finally, signs of purulent absorption appeared, and she died two months after the puncture.

Dr. Homans, of Boston, reports a case of stricture with perineal fistula and large calculi in the pelvis of each kidney. The patient, sixty-six years, began to have difficulty in micturition six years ago. From that time gradually failing. Urine purulent, ammoniacal, and voided with pain. A year ago perineal abscesses discharged externally; in two months, after great pain and swelling in the perinæum, the urethra ruptured, and the urine escaped through a fistula. A catheter was finally made to pass the stricture, but the patient gradually failed and died.

Both kidneys were found to contain calculi of various sizes and shapes. A single one formed a complete cast of the cavity in which it was found—the left pelvis—and resembled some coral formations. It was two and a half inches long by one and a half wide; weight, one ounce. Many of the branches were cup-shaped, articulating with portions more deeply imbedded in the kidney, or receiving the papillæ of the pyramids. In the *right* kidney were irregular masses, from $\frac{1}{8}$ of an inch in diameter, downwards. A puruloid fluid filled the surrounding spaces. No pus cells were found, but many oil globules, granules, and crystals of triple phosphate. The adjacent renal tissue was gangrenous. The ureters contained the same offensive fluid and calcareous debris. Bladder thickened, mucous membrane dark green, and in many cases cribriform. The same fluid here. Middle lobe of prostate enlarged, but gland itself small, size of large filbert. Just anterior to membranous portion a fistula and sinus; the stricture probably here. Stone composed of urates, carbonate and oxalate of lime, and triple phosphate.

Mr. Southam records three cases of what appears to have been spontaneous fracture of vesical calculi in situ. Two were hard and compact, of uric acid and oxalate of lime, and had evidently been broken some time before their removal. Mechanical violence is eliminated as a cause of fracture, which Mr. Southam attributes to the generation of gas in the calculi themselves, either from chemical change of earthy constituents or decomposition of animal mucus, their cement.

Dr. Homans, of Boston, removed a small calculus from the meatus of a boy of four years, who had retention for twenty-four hours. The phymosis and œdema were so marked that it was difficult to find the preputial orifice. The patient was in great pain, with a hot skin and quick pulse. He was etherized, the prepuce slit up, and a calculus about one and a half lines in diameter, with facets, was found, completely occluding the meatus, and tightly imprisoned by the swollen prepuce. The urine began dribbling at once upon its removal, but was withdrawn by a catheter, to the amount of thirty-six ounces, with entire relief to the patient. The stone was of urates and oxalate of lime.

Dr. Leon Serbet, Aise, France, has used ergot in paralysis of the bladder with success. His patient was sixty-six years of age, and had been suffering from incontinence of urine for fifteen years. The doctor was called on account of paralysis resulting from over-distention during an attack of retention of urine. Ergot was tried, thirty grains during the day; no effect. At the end of ten days, fifteen grains were given four times daily at twenty minute intervals, before and after a hip bath in the morning. From this time he could urinate, and was cured in fifteen days. Ergot is thought to cure paralysis of the muscular fibres both of the body of the bladder, and of its neck.

Dr. Abbotts Smith calls attention to certain moral and dietetic points in the treatment of this disease. The bad habit of not getting out of bed to empty the

bladder at proper intervals should be counteracted. The quantity of fluids should be moderated, especially at night. This constitutes the secret of the "Dieta Sicca." This plan is useless when enuresis depends upon organic disease of the parts. Milk is recommended as unstimulating and easy to digest. Hot liquids taken as drink, especially tea, are objectionable. Patients should be cautioned against horseback riding.

Dr. Butler, of Maryland, relates a case of horseshoe kidney, in which the organ was in the pelvis, and could be felt per rectum. Four arteries supplied this anomaly, a single large trunk, from the aorta at its bifurcation, which was immediately in front of the sacra media, two from the left, and one from the right internal iliac.

There are now two specimens of the horseshoe kidney in the museum of Charity Hospital, at least one in the Wood Museum, and we believe one in that of the City Hospital.

Two cases of movable kidney were recently mentioned by Mr. Heckford, in the *Lancet*. The right was most freely movable in both, and in one, a woman, could be pushed on to the vertebral column.

Addison's Disease of the suprarenal capsules is the subject of a work by Dr. Edward Greenhow. An analysis of 196 cases is given, with every item of possible interest connected with each case. The object is to remove the doubts which many have entertained as to the reality of this disease, in order that, its existence being fully recognized, future inquiry may with more assurance be directed toward the investigation of its causes.

The *American Journal of Medical Sciences* contains two reports which serve as comments upon the foregoing. In one case there was extensive disease of the capsules without the slightest discoloration of the skin. The left was enlarged, and the right from two to three times its usual size. They were firm, and contained a large amount of opaque tubercular-looking matter.

The other case was of cancer of the pelvic viscera in an aged female, with a cancerous nodule one-half inch in diameter upon the peritoneal face of the right kidney. The organs were otherwise healthy. The suprarenal capsules had suffered a little fatty alteration, such as is commonly found after middle life; otherwise normal. There was intense bronze discoloration over a very large extent of surface, varying in depth of tint; very deep in the scar of a blister.

Albuminuria.—Fauvel gives the name *Aphonia Albuminurica* to aphonia depending upon œdema glottidis, which appears in incipient Bright's disease. Besides the tense swelling of the mucous membrane, with a pale smooth surface, the laryngoscope shows no local morbid process. The urine is found albuminous.

Professor George Johnson writes as follows upon the treatment of *Diarrhœa and Vomiting in Renal Disease.* From the *British Medical Journal:*—"Bearing in mind that the vomited matters are usually very offensive, if you direct to take copious draughts of tepid water your patient will often obtain relief by the speedy expulsion of foul secretions, and the thorough washing out of his stomach. This should be repeated from time to time. The food must be of the lightest and most digestible kind." He recommends hydrochloric acid, fifteen or twenty drops, with each meal, with one-thirtieth grain strychnia. The acid neutralizes the ammonia often thrown off abundantly. Sometimes vomiting will be relieved by a purgative enema, or, if the stomach will bear it, the compound colocynth pill to stimulate the lower bowel. Nutritive enemata are of use to support strength when vomiting is incessant.

The irritation of the bowels may be as great as that of the stomach. Tenesmus may sometimes be allayed *by the very guarded use of opium*, the effect being carefully watched, as there is great danger attending its incautious exhibition. The object is to allay irritation, not to close a safety valve. All this disturbance will disappear if the kidneys can be made to act. Besides the usual expedients, as counter-irritants, diuretics, hot-air baths, and the like, he highly recommends an incision into each leg when there is much anasarca. The fluid is rapidly drained away, the vessels unloaded, congestion relieved, and so a more copious secretion. The result of his experience is that in cases not complicated with valvular disease of the heart, inflammation rarely follows puncturing the legs, and the relief which follows the operation is often very great.

Glucosuria.—In August, 1861, G. Meissner announced his discovery of a true sugar in muscle. Dr. Johannes Ranke has reinvestigated the subject, and fully confirms Meissner's supposition. The following propositions are considered as established:

1st. That there exists a true fermentable sugar in muscle.

2d. That the amount of this sugar is increased by muscular action, including tetanization caused by strychnine or electricity.

3d. That the liver has no effect in causing this increase; for the sugar is proved to arise in the muscle itself, and from the muscular substance.

M. Collas, alluding to this fact, and the other that the substances required for the nutrition of the organs reach them in a soluble condition and are fixed by some substance unknown, advances the theory that phosphate of lime is the agent in question, since it converts sugar into the nearly insoluble glucose, thus precipitating and fixing it in the organs. He recommends phosphoric acid and the phosphates, and reprobates forbidding bread. On the strength of this Mr. Carey Lea, of Philadelphia, suggests that by parity of argument the mineral acids and alkaline nitrates might serve to fix albumen in Bright's disease! M. Guyot-Danecy proposes to employ citrate of soda as the fixing substance in diabetes. The citrate is substituted for the carbonate because it does not interfere with digestion. He administers from one to two drachms at a dose, which may be mixed instead of salt with the bread. With its use starch food ceases to be objectionable. He alleges that the sugar disappears from the urine after the exhibition of this salt.

Diabetic Phthisis.—The first general symptom of this rare disease, says Dr. B. W. Richardson, is severe hectic, the hot stage of which is extreme, and is succeeded by great coldness of the surface, depression, and copious elimination of urine. Dyspnœa is a marked symptom; a hacking, dry cough, is common. Hæmoptysis, properly speaking, he has not seen; but rusty sputum in small quantities is frequent. There is little acute thoracic pain, but great oppression. Wasting is extreme. The physical signs are marked. Cavities are not often found, death taking place too early to allow softening to occur; moreover the diabetes interferes with this process by removing water.

In pronounced cases the prognosis is inevitably bad, and generally definite, too, as to time: he has not seen a case survive four months after the tubercular condition was established. From six to ten weeks was the common term after hectic began to recur with regularity. In every case of the disease he had seen, there had been disease of the base of the brain. In one case there was bone pressing upon the under surface of the medulla oblongata; in another, softening of the brain substance; and in a third, disease of the vessels, with thickening of the membranes, and old adhesions. One of the patients had recovered from acute meningitis, to be taken immediately with diabetes.

That there is a functional and an organic type of diabetes; that the functional is largely curable, and the organic absolutely incurable; and that the functional type is connected with a false digestion, owing to a temporary interference with nerve action—these, he thinks, are facts which every scientific physician must be prepared to accept.

He is convinced that oxygen, iodine, or chlorine, with their compounds, do harm; they increase elimination and reduce accordingly. He discards a restricted diet. He sustains the warmth, and checks the waste of the body by opium and quinine; he supports by good food, especially the animal oils, which he gives as the Esquimaux take it, and for the same reason, to sustain the lost caloric. He thinks there is more hope in this than in any other remedy, used by the half-pint at a time. Dr. Abbotts Smith says that no remedy in the materia medica is of such value as this. It has a tendency to improve the blood by increasing the proportion of red corpuscles. His system of alimentation is exclusive of the starches.

Dr. H. Bence Jones says that the effect of dieting upon this disease is far beyond that of any known remedy. The potassio-tartrate of iron and Griffith's mixture are recommended, taken with some gaseous mineral water. Vegetable and animal oils and fat constitute important remedies; of these, cod-liver oil and cream are the best. A man, aged twenty-four, was admitted into St. George's Hospital, having lost two stone during eight months. He passed seven quarts of urine daily. He remained under treatment a month, during which time he was on animal diet and cod-liver oil. He began with half an ounce daily, and increased gradually up to eight ounces. The urine fell to two and a half pints, sp. gr. 1030, and he increased in weight from eight stone eight pounds to nine stone one pound.

Mr. Hare speaks most highly of the dietetic method. By perseverance, he reduced the sp. gr. in one case to 1007, yet there was a trace of sugar present. This is the lowest sp. gr. on record in which sugar has been found.

Prof. Bouchardat recommends energetic and systematic exercise, coupled with a diabetic regimen. Clarets are allowed, but not sparkling wines.

Sir Henry Marsh advocates the frequent use of the vapor bath and muscular exercise. It should be used not occasionally, but daily, for weeks or months, if necessary. This advice is founded upon the good results obtained in a case under his charge.

Dr. Ramskill has treated some cases very successfully with a mixture containing three grain doses of permanganate of potash, in water, and with increasing doses of extract of cannabis indica, in pill, beginning with a quarter of a grain three times a day, and going up to three grains.

Dr. Buttura, French, cured a ten years' diabetes with a seton to the neck. The sugar went as the pus came, and the patient remained well eight months after the withdrawal of the irritant.

Beranger Ferand has treated two cases of diabetes with partially favorable results, with tincture of iodine, five to fifteen drops of the French preparation, before each meal. In two other cases he found the sugar to diminish by large inhalations of oxygen—twenty quarts of gas night and morning. He does not think this treatment will *cure*, but that it is of great benefit.

Prof. J. H. Salisbury appears again as a discoverer of the zymotic nature of disease. This time it is rheumatism, which malady he considers four-fold, as characterized by the presence at one time of lithic acid, at another, oxalic acid in lime combination, or cystine, or phosphates. The characters of each are drawn out at some length. The fermentative part is taken by an oïdial cryptogam, consisting of spores and filaments, which are found in the blood and urine, together with the offending crystalline substances aforesaid. The name is *Zymotosis translucens*. It soon becomes invisible when placed between the slides. The following directions are given: "The blood should first be carefully examined under the microscope. To do this an incision is to be made in the arm, a drop of blood quickly pressed out, and received upon the slide. This should at once be covered and placed under the instrument and carefully watched, to observe the manner in which the red discs arrange themselves, and the condition of the colorless corpuscles. Very soon, amid the red discs and fibrin cells will be seen, here and there, masses of minute spores, and occasionally, ropes and knots of algoid filaments. Crystalline matters are also occasionally met with." The characteristic fungus is also found in the urine. How it differs from penicilium glaucum is not stated. The treatment is certainly "mirabile dictu." In three of the "species" it begins with four distinct prescriptions, one containing six ingredients. You look in vain, however, for those sovereign anti-fermentatives, the sulphites of soda. They are for once left out in the cold. To enjoy a diet of raw beef, finely chopped and mixed with yolks of soft-boiled eggs and cream, with other food, excluding, however, all sweets and acids; to be pounded thrice daily with a ball of curled hair, attached to a stick; to be blistered or fortified with tonics; to have warm baths occasionally, and frictions often, and finally to be resigned to some months, a year, of this interesting ritual—are some of the delights of the rheumatic.

M. Bordier, in a memoir detailing his experience of the cholera epidemic of 1866, refers to the changes in the urine before and during reaction. *Before this* it is found in all cholera patients to be albuminous. This is thought to be due to a parenchymatous nephritis, such as occurs in scarlatina. Heat does not always reveal the albumen. Nitric acid, however, precipitates it, but besides this cloud there appears, in severe cases, a sediment of a mahogany color. This color changes to blue, and then the bottom of the glass is covered with a layer of indigo-blue, soluble in ether, and almost entirely composed of pure carbon. *During reaction* this fluid contains double the normal amount of urea, with uric acid, substances rich in oxygen. Albumen is still present, though only for a short time and in small quantity; but sugar now appears. The thirst is again felt, and the body is covered with boils. Glucosuria is a constant symptom in reaction, as albuminuria is in the algid state. This is thought to be due to paralysis of the vaso-motor nerves, which characterizes this period, and which acts upon the liver as well as the other viscera, and causes passive dilatation of the blood-vessels.

Urinary Sediments.—In the *Lancet* for Feb., 1867, is figured a tube and stand for the more expeditious collection of objects for microscopic examination. It resembles the chemist's burette, but is furnished with a stop-cock below. We have used a burette with the German spring valve, and prefer it, with a short point, to the English arrangement.

Dr. D. W. Flora, of Chicago, remarks that the dumb-bell crystal of so-called oxalate of lime is not a primary but a tertiary form. He claims that they are a modification of the globular, stellate crystals of urate of soda, which become after a time joined two-and-two by an isthmus. "The primary form is acicular, the secondary globular, and the tertiary the *famous* dumb-bell." Dr. Flora does not seem to be aware that a dumb-bell

form of the urate of soda has been known for some years, and is figured by Hassal in his work on the urine. Six kinds of dumb-bell crystals are found in human urine, and a seventh in that of the horse, carbonate of lime. Uric acid, phosphate of lime, oxalate of lime, sulphate of potash, and the urates of soda and of potash, are the six referred to.

The tests for the oxalate are liquor potassæ and acetic acid, both with heat; neither has any effect. If Dr. Flora had made use of these, he would probably have seen his dumb-bells rapidly dissolve; the best proof that they were not oxalic. We have proof that the oxalate dumb-bell *is* a primary form in that it has been found in hyaline casts of the tubules.

Dr. F. Bateman, in the *Lanc t*, reports a case in which sarcinæ were, at intervals, found in the urine of a gentleman suffering from dyspepsia and neuralgia. He had a long-standing stricture of the membranous portion; and a frequently-recurring prostatic irritation had recently been relieved by the passage of several small prostatic calculi. This affection is quite rare, and no attempt has been made to explain its origin. Bennett has seen but one case. Bea'e mentions a few instances; Neubauer and Vogel only allude to two cases.

With regard to the *source of muscular energy and its relations to the excretion of urea*, the experiments of Frankland, Fick, Wislicenus, and Parkes, seem to prove, that during exercise the urea is diminished, or but slightly increased, and that muscular power is not therefore so much derived from oxidation of albuminous as of non-nitrogenous material. Hence it is argued that the urea cannot be taken as a measure of the force expended, or the waste occasioned. Also that persons training for muscular feats should not live upon a diet restricted to albuminous substances. The experiments of Dr. Noyes detailed in the *Am. Journal Med. Sciences* seem to prove that such a diet will increase the excretion of urea considerably, part, at least, of the increase indicating the excess of albuminous ingesta.

These are some of the more interesting facts and opinions, relating to our subject, which have been hurriedly gleaned from a large number of foreign and domestic journals.

RUPTURE OF VAGINA DURING LABOR.

CHILD PARTLY AND PLACENTA ENTIRELY WITHIN THE ABDOMINAL CAVITY.—DELIVERY BY FORCEPS, AND RECOVERY OF THE PATIENT.—SUBSEQUENT PREGNANCY, AND DELIVERY OF A STILL-BORN CHILD BY INSTRUMENTS.

By T. B. STIRLING, M.D.,

NEW YORK.

On January 10, 1863, my services were required in the case of Mrs. P——, then in labor. The pains were violent and ineffective. The cause of the difficulty seemed to be the anteversion of the uterus. The abdominal walls were very pendulous, extending upon the thigh nearly half way to the knee, giving the tumor of pregnancy an ovoid shape, much elongated. This prevented the head from engaging in the superior strait; examination showed that it could not be reached per vaginam. The pendent tumor was raised and supported in this position, so as to bring the axis of the uterus more nearly in line with the axis of the strait, and thus favor the passage of the head. The labor now went rapidly forward, and a living child was born in less than an hour.

The woman was of tall, spare figure, thirty-six years of age; had given birth to six children, and joined to the usual household labors of her class, the occupation of a tailoress, assisting her husband in the common living room, which was also the workshop. To hard work, and to the necessity of maintaining a sitting posture when at work, she attributed the extreme laxity of the abdominal walls, and the pendulosity of the tumor of pregnancy, which caused the difficulty of her labor.

The circumstances of this case had passed out of mind for two years and a half, when, on the 9th of July, 1865, my services were again desired, but being out of town, I did not see the patient until late. On arriving at the house, I was informed that labor pains had commenced at 12 M., recurring every half hour, but not deemed sufficiently severe to require assistance. About 5 P.M., while she was sitting on a chair, the waters broke, without a pain. At 7 P.M. the pains became suddenly so violent, that she alarmed all around her by her unusual and agonizing outcries. So continuous, sharp, and forcible were they, that any preparation of her bed or person for the exigencies of labor was deemed impossible. At the time of my arrival, 9 P.M., the pains had nearly ceased, but she had the appearance of having passed through great excitement, and her expressions concerning her sufferings were a little wild for one who had borne six children, and was habitually self-restrained and reticent.

A hasty examination was made, and the finger came promptly in contact with the corrugated scalp, just within the vulva. The excessive pendulosity of the abdominal walls was noticed, which recalled the previous confinement, and the kind of assistance then rendered. A tumor over the pubes was faintly noticed in the median line, with the apex below and the base as high as the umbilicus. The true significance of this was not appreciated at the time, but the idea of an abnormal tumor obstructing the labor occurred to my mind. It was ascertained by examination not to be distended bladder. Its shape was more like a uterus, after delivery, before it has fully contracted. Nothing of a positive character being determined, the examination was discontinued, the patient complaining of pain under the touch, and there being no pressing necessity of pursuing it further. The labor pains had now entirely ceased. The attendant female was directed to support the pendent abdomen, as had been done in the previous labor, and traction was made with the fingers, used as forceps. Pains were feebly excited by this means, but the head was not advanced.

Taking advantage of this interval of rest, the patient's attendants were directed to make her bed more comfortable, and to change her dress, while I awaited in the other room, the expected early renewal of the pains of labor. The patient made not the slightest complaint, and apparently was sleeping. Thinking the pains were delayed too long, about 12 o'clock an examination was made, which revealed the fact that the head had somewhat receded. The tumor over the pubes was still well defined, and a hard projecting point was felt just above the umbilicus and a little to the left of it, very near the surface. Rupture of the uterus was at once suggested, and the irregularity of the abdominal walls was recognized as some portion of the lower extremity of the child. The countenance of the patient was quiet and not indicative of exhaustion; the pulse rather weak, but without excitement. The fœtal heart could not be heard. Being convinced of the diagnosis of rupture, which had probably taken place several hours before, and there being nothing in the condition of the woman to excite immediate apprehension, I left her and went in search of medical aid. Dr. Thomas F. Cook came to my assistance, reaching the house about

3 1-2 A.M. He examined the case, and confirmed my diagnosis. He also was of opinion that the moment of rupture was during the sudden access of pain described above as occurring about 7 1-2 P.M.—an hour and a half before I reached the house. Dr. C. gave chloroform, and the child was withdrawn by me with the forceps without difficulty. It exhibited no signs of life—the ordinary means of resuscitation being tried without success. The appearance of the child favored the opinion that it had been dead some hours.

In completing the delivery, the cord was followed through the rent into the abdominal cavity by the left hand. It led, by turning a sharp corner, to the lowest part of the sac formed by the pendent abdominal walls. Here the placenta was grasped within the peritoneal cavity, brought up through the rent and so delivered. In doing so, the following points were noted. The os uteri was found to be closed; the rent was situated in the vaginal space behind the cervix; the promontory of the sacrum presented to the hand in passing a very sharp angle; the fundus uteri was grasped in the hollow of the hand and ascertained to be unruptured; the placenta was small, and the blood squeezed out of it, as a sponge. The delivery being completed, Dr. C. examined the rent and verified the fact of the rupture and its locality in Douglass' space. In applying the bandage, the laxity of the walls was made very apparent. It was necessary to direct the attendant to steady the sac full of intestines in the abdominal space like a bag of meal, while the binder was applied very loosely. The abdominal walls formed a fold over the pubes, extending several inches downwards on the thighs.

No hope of recovery was entertained by me, Dr. C. thinking it barely possible. Anodynes and stimulating nourishment were ordered. The patient was assiduously watched, two or three visits being made each day, but some difficulty was experienced in controlling the sister, who officiated as nurse, so as to secure the proper administration of a stimulating regimen. The patient, however, remained quiet and free from pain till the fourth day. Then tympanites and prostration were noticed, and turpentine stupes, and afterwards a cataplasm, were applied over the entire abdomen. This afforded temporary relief, but on the sixth day the lowest degree of prostration was reached and apprehension was entertained that the end was near. But under vigorous stimulation, she rallied and recovered from this condition. On the ninth day an attempt was made to relieve the distressing tympanites, by inserting the tube of a stomach-pump far up the rectum. This secured the desired passage of much flatus, but next morning she had a profuse diarrhœa, with pulse at 106, and a distressing palpitation of the heart. These symptoms were relieved by Tr. Opii—gtt. xxv., 2dis horis. On the twelfth day, at a point about three inches below the umbilicus, the abdominal walls were noticed to be exceedingly thin, and a nipple-shaped protrusion was forming. The fold lying over the pubes was red, thickened, and distended. The general tympanites became enormous. This protrusion proved to be an abscess, which went on increasing till the evening of the fourteenth day, when it burst externally, discharging a very large quantity (said to be enough to fill a wash basin once and a half full) of thin, greenish, fœtid fluid. This was probably made up of the putrid products of peritonitis, the meconium of the child, and the blood that escaped from the placenta when in the abdominal cavity. For three days before the bursting of the abscess, the pulse kept steadily at 128; the great prostration reappeared and dissolution seemed imminent. On the twelfth day, the first digital examination was attempted, to ascertain the condition of the rent, and a hernial tumor was discovered *filling the entire vagina to the vulva*, at first giving the impression that the intestine had fallen through the rent.

In these newly discovered complications the counsel of Drs. Cock, Little, and McLeod was sought in turn. Many examinations were made, as far as possible, without the speculum, the patient refusing to permit its use. No positive opinion of the character of the tumor in the vagina was arrived at, but the impressions left on my own mind by the consultations were these. The tumor in the vagina was probably entirely omentum, altered by inflammation. It had fallen through the rent, completely plugging it up, and preventing the exit of the material which afterward composed the contents of the abscess. The cavity of the abscess was probably confined to the abdominal walls, but communicated by some free channel with the peritoneal cavity. In the vagina the rent was distinctly traceable all around the base of the tumor, to which the edges of the rent seemed to be agglutinated. The elongated slit of the os uteri was readily recognized in front of the tumor, and the uterus was, after some doubting, agreed to be not adherent to the abscess by its posterior wall. There had been a sanious discharge from the vagina on the second day after delivery, probably originating in the uterus, but the great discharge constantly expected did not make its appearance, being effectually stopped by the occlusion of the peritoneal cavity, by the omentum protruding through the rent.

A colpeurynter pessary was placed in the vagina for a few days, farther protrusion of the viscera being apprehended. Both the abscess and the vagina were freely syringed every day by the deep insertion of the vaginal nozzle. The cavity of the abscess was often swept by the finger in course of examination, the mouth being at least an inch and a half in diameter. Poultices were kept constantly applied up to the twenty-seventh day, when Bals. Peruv. was substituted. The patient rapidly convalesced after the breaking of the abscess, experiencing no inconvenience in her functions from the tumor in the vagina, and sat up for the first time on the twenty-eighth day.

(Fifty-sixth day)—Sept. 2d. I found her at work, in nearly her usual health, but also found myself in disfavor, because she had recovered in spite of my unfavorable prognosis, and I therefore did not venture to propose, as I much desired, an examination of the parts. On June 9, 1867, two years after, I called again, to ascertain her present condition, so as to be able to complete this history, and was much astonished to learn that she had been, in the intervening period, delivered by instruments of a still-born child. I applied to the gentleman who officiated on that occasion, and he kindly furnished me with a detailed statement of her confinement, which took place on the 30th Nov., 1866. He had received no history of the previous labor to guide him, as it was designedly kept from him by the parties. He says in his report, that the pains died suddenly, in about an hour after they had become strong and forcible. He waited three quarters of an hour, and then he had recourse to forceps, becoming convinced that the child could not be delivered without instruments.

He is of opinion that Mrs. P—— can be delivered of living children, but only with instruments *applied early*. The grounds of this opinion are not stated. The death of the child is attributed to the premature separation of the placenta, a few minutes before the birth of the child. The abdominal walls did not strike him as abnormally large or lax. No cicatrice or tumor was remarked. No difficulty in coition had been experienced by the husband, and the possibility of conception had been fully demonstrated.

Original Lectures.

LECTURES ON TUMORS:

BEING PORTION OF THE COURSE ON SURGERY AT THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

SESSION 1867–8.

BY S. D. GROSS, M.D., LL.D.,

PROFESSOR OF SURGERY.

(Reported expressly for the MEDICAL RECORD.)

II.

NO. II.—VASCULAR TUMORS.

CONCERNING these I have little to say. The vascular tumor is an uncommon form of tumor, comparatively speaking. We observe it most frequently as a mother-mark, a viscus as it is called, a little speck existing upon the skin, generally of the forehead, or of the nose, or the eyelid, or the lip, or the cheek; it may be, the ear, sometimes the neck, sometimes the shoulder, or the trunk, or an extremity; sometimes several of them occurring simultaneously in different portions of the body; sometimes on the inner surface of the cheek in connection with the mucous membrane. The best example I can give you is an internal hæmorrhoid or pile, the result of frequent straining, producing thus a determination of blood to the inferior portion of the rectum, followed by habitual distension of the capillary vessels in the submucous cellular tissue, as well as in the substance of the mucous membrane, so as to form a tumor the size of a common marble, or a pullet's egg; composed essentially of a congeries of capillary veins or arteries, united and supported by cellular tissue, bleeding copiously when incised or excised. A nævus may be composed essentially of capillary veins or capillary arteries; or it may be composed of a combination of the two, the one or the other usually predominating. When a tumor is composed of veins its color will be purple, or modena, or livid; when it is of arterial tissue, it will be scarlet, and there will, at the same time, be pulsation synchronous with the contraction of the left ventricle of the heart. Such a tumor constitutes what was originally described by John Bell, of Edinburgh, as aneurism by anastomosis. When consisting both of veins and arteries there may be slight pulsation, or an absence of pulsation.

Such tumors require excision when they are situated favorably; or instead, you may transfix the base of the growth, when it is comparatively small, at two opposite points, with two pins, and wrap around them a strong ligature to strangulate the affected tissues, performing the operation in the manner you have seen me execute it at the Clinic.

III.—ADIPOSE OR FATTY TUMORS.

The adipose or fatty tumor is of sufficiently frequent occurrence. It consists of a mass of fat similar to that in the parts around, being simply an outgrowth of the natural, preëxisting or original fat. Under the microscope it is found to be composed precisely of the same cells with the same characteristics; chemically it consists of the same constituents precisely, and it has the same properties precisely as that tissue. Why it should grow into a tumor, we cannot of course determine. A tumor of this kind may be single or multiple. In one case I saw upward of two hundred in the body of the same individual, a medical student who attended my lectures in the University of Louisville. In such numbers they are unusual. Generally the tumor is single, situated most commonly in the subcutaneous cellular substance. Sometimes such a tumor is pendulous, hanging off from the body in a mass of considerable size. Generally speaking, it has no very distinct capsule; there is usually a slight condensation of the cellular tissue around it, so that it might be called a distinct envelope. Such tumors have comparatively few large vessels; nevertheless they are capable of acquiring a large bulk. When we remove such a tumor we do not expect much hæmorrhage, for the vessels distributed through the tumor are generally very small. It has its nerves and absorbents, which are not of new formation any more than the tumor itself. It may acquire a bulk of twenty, thirty, forty, or even seventy pounds. Dr. Bray, of Evansville, Indiana, removed one some years ago, weighing forty pounds; and Prof. Leidy, of the University of Pennsylvania, presented me with a section from such a tumor weighing seventy pounds, removed from the cavity of the abdomen of a man after death. Its growth is slow, a number of years usually elapsing before it attains any considerable bulk. When subjected to frequent or constant pressure, as when it is situated on the shoulder, it may take on ulcerative action; but ordinarily it grows on, gradually developing itself, without any untoward occurrence of this kind. It is not capable of assuming malignancy under any circumstances.

The proper remedy is excision. Nothing else has been found to answer the purpose.

I need not call your attention to the different forms or configurations of these tumors. In the groin and neck they send out processes in different directions, which we are obliged to dig out, as it were, during the operation of extirpation.

IV.—HORNY TUMORS.

The horny tumor, or horny excrescence, is a very curious formation, apparently entirely epithelial in its character, an outgrowth from the epidermis, and from the sebaceous follicles. There is still some obscurity with regard to the origin of a growth of this kind, but such we are willing to believe is the method of its development. Tumors of this kind are capable of acquiring considerable dimensions. There are records of their being ten, twelve, fourteen, and sixteen inches in length, and of proportionate diameter; sometimes as a single horn, at other times multiple with ramifications precisely like the horns of the inferior animals. The color is usually brownish, from exposure of the part to the atmosphere; and if a section is made, it will be found to be longitudinally laminated, growing in that way by layers. The surface is frequently rough, imbricated, or scaly. It is, of course, entirely insensible; it has no vessels in its interior, so far as we are able to determine, but its base is, of course, more or less vascular. Chemically, it is found to be composed chiefly of albumen, with phosphate of lime in combination with some sulphates. Under the microscope, it is seen to consist of an immense number of exceedingly minute epithelial cells of various shapes, round, oval, and conical. The most common situation of such a tumor is the scalp, frequently the forehead, sometimes the face, sometimes the upper or lower lip, sometimes the shoulder, sometimes the extremities, sometimes the buttock. I show you one I removed from a lady now nearly ninety years of age; it grew from the side a short distance below the left mammary gland, and she has another one growing in the right axilla. A tumor of this kind has been found upon the penis and upon the vulva; indeed, there is hardly any part of the body where it has not at times been found.

The proper remedy is excision, cutting out the parts from which it has sprouted.

V.—FIBROID TUMORS.

The fibroid or fibrous tumor consists of tissue similar to the fibrous tissue in the natural state. It is composed of fibres or threads crossing each other in every conceivable direction, forming thus a very tough, strong, condensed resisting tissue, grating under the knife. A tumor of this kind has occasionally a distinct capsule, but generally it is devoid of a covering of this kind; the cellular tissue around it is always more or less condensed. The tumor is provided with blood-vessels, nerves, and absorbents, precisely as the fatty tumor, and these are sometimes of new formation; at other times derived from the surrounding structures, shooting into them, as in false membrane of the pleura or peritoneum. Tumors of this kind grow slowly, years sometimes elapsing before they attain considerable volume or expansion. By and by such a growth will take on an increased activity, and then develop itself with great rapidity. It is capable of acquiring a large bulk. A case reported by the late Dr. Francis, of New York, connected with the uterus, weighed 105 pounds, nearly as much as the woman in whom it was developed.

These tumors are liable to occur in various parts of the body; sometimes under the skin, sometimes in connection with the testes, or ovary, or uterus, or some other internal organ, the periosteum, the interior of a joint, etc. The largest growths of this kind occur in the uterus, either in the interior of the organ, in its wall, or upon its outer surface.

There is a fibrous or fibroid tumor which bears the name of *fibro-plastic*. This tumor is simply a modification of the original fibroid tumor as described. We have an illustration of this variety of tumor in the keloid growth, or crab-like tumor. It contains fibrous tissue in combination with plastic tissue, a large quantity of fibrin in a state of organization, more crisp than the fibroid tissue, not as tough.

Now and then we meet with what is called the *recurring fibroid tumor*, a very singular kind of growth. A man comes with a fibroid tumor on the shoulder, or upon the face or back of the neck, if you please; this tumor may be the size of the fist, or it may not be larger than a goose's egg or a pullet's egg, comparatively small; it may be of two or three years' standing; it may be entirely free from pain, with no discoloration of the skin, nothing at all showing that it has any malignant tendency. The tumor is carefully removed, completely excised, every particle being disposed of in this way. In the course of twelve or eighteen months, or two or three years, as the case may be, a tumor of precisely a similar kind will arise in the same spot from which the other was removed. Such a tumor, we say, is a recurring fibroid tumor. A second tumor of this kind may be carcinomatous, that form known as encephaloid.

In the removal of such a tumor there may be a good deal of difficulty; it may be deep seated, may send ramifications among the surrounding structures to a considerable extent; may involve the muscles, nerves, arteries, and veins, so that a nice dissection is required. The proper remedy is excision; nothing less.

VI.—CARTILAGINOUS TUMORS.

The cartilaginous or enchondromatous tumor, or the enchondroma, as it is called by Müller of Berlin, by whom it was first accurately described, stands intermediate between the fibroid and the bony or osseous tumor. The largest tumor of this kind I ever saw was in a young man, a native of Massachusetts, who died six weeks after visiting this city: it involved the right shoulder, and was found to weigh thirty-one pounds; a mass which could have been removed very readily, as was shown by Dr. Jackson, of Boston, had an operation been performed at the proper period. These tumors occur in different portions of the body, most generally in connection with a bone, sometimes in the intermuscular cellular tissue, sometimes in the ovaries, uterus, mammary gland, or other organs of the body. They are slow in formation, non-malignant in their tendency, giving rise to pain, but chiefly incommoding by their weight and by their pressure; so far as we are able to determine, they are not disposed to run into malignancy, or to degenerate into carcinoma. A tumor of this kind frequently contains a large quantity of bony matter, especially when the growth is of long standing, when it is liable to degenerate into a bony, osseous, or a calcareous formation; but in its earlier stages it is of the appearance of cartilage or fibro-cartilage, as the fibro-cartilage of the nose or larynx. As it increases in age it becomes more hard, firm, and resisting, until it degenerates into bony substance. Examined with the microscope, we find it is composed, like all the other tumors, of cells containing nuclei and nucleoli of variable size; chemically considered, it is found to be composed of chondrin, a peculiar form of jelly, the precise character of which has not been determined. It is more dense, firm, and resisting than the fibroid tumor; less so than the bony. There is no distinct cover in a tumor of this kind, but the cellular tissue which lies in immediate contact with it is always more or less condensed; but there is nothing like a distinct capsule or envelope, except in very rare cases. Such a tumor has its proper blood-vessels, nerves, and absorbents. The blood-vessels are never of large dimensions; consequently, when a tumor of this kind is cut into, it does not emit much of this fluid; and therefore, when it is extirpated, provided the knife is kept in close contact with its periphery, there will be very little hæmorrhage, even if the tumor is of very large bulk.

Such a tumor is not amenable to the absorbent vessels, and the sooner it is removed, the better for the part and system; if it be developed from a bone, this must be removed with it.

VII.—OSSEOUS OR BONY TUMORS.

Growing from the posterior portion of the shaft of a thigh bone which I hold in my hand, is a ledge of bone, a small tumor, very narrow and thin, having almost a sharp, free margin, and connected with the bone from which it grows. This is an osseous or bony tumor. Very frequently the term exostosis is applied to this form of tumor, from a Greek compound, signifying to grow from a bone. It consists of precisely the same material as the bone from which it grows. A tumor like this is susceptible of acquiring great bulk, as in one of the specimens of the disease of the thigh bone exhibited, and sometimes acquires a much larger development, and when this is the case it is easy to conceive the encroachment it would make on the surrounding structures. It would produce great pain and tenderness in the part, leading to a necessity for the removal of the tumor, or the amputation of the limb. I show you an hemispherical tumor taken from the posterior part of the skull of an elderly subject, who had carried it for many years. It is a specimen of condensed bony tumor, containing a large quantity of carbonate and phosphate of lime. The word ivory is used to designate this form of tumor; it is the eburnized variety of exostosis. Tumors of this kind are of slow growth; there is no tendency to malignancy; they may remain latent for many years. After a while they may acquire an increased activity, and in this way ultimately attain a very large bulk.

Such a tumor, when found to incommode the parts by its pressure, its interference with important func-

tions, requires removal; and in some cases, as when connected with an extremity, amputation of the limb.

VIII.—CALCAREOUS TUMORS.

The calcareous or earthy tumor is exceedingly uncommon. I have seen but very few cases of it, and I have no specimen to exhibit to you. We find this form of tumor occasionally in connection with the lymphatic ganglions of the neck in a state of degeneration; we find them occasionally in the interior of the uterus and of the ovary, consisting of calcareous matter, composed mainly of carbonate and phosphate of lime arranged in such manner as to be exceedingly brittle, having none of the osseous tissue properly so called. This form of tumor is interesting in a pathological rather than in a practical point of view.

IX.—NEUROMATOUS TUMORS.

The nerve tumor, or neuromatous tumor, or simply the neuroma, presents us with two varieties, the neuromatous tumor proper, and the subcutaneous painful tubercle, or a peculiar form. The neuromatous tumor is connected with the large nervous trunks, as, for example, the sciatic, the median, and the radial and ulnar nerves, which are the structures more particularly liable to suffer; but sometimes we find them in connection with the smaller nerves, and sometimes in large numbers in the sympathetic system. Sometimes they are solitary, at other times they are multiple. Dr. Robert Smith, of Dublin, by whom these tumors have been better described than by any one else, has given a case in which there were upwards of one thousand found along the course of the great trisplanchnic system of nerves. There would seem, therefore, to be occasionally a neuromatous diathesis. This tumor, if it be carefully examined, will be found to exist simply in an expansion of the nerve fibres, which are spread like feathers, or the ribs of a fan, inclosing a large quantity of fibroid tissue, a substance similar to that entering into the composition of the fibroid tumor. Under the microscope it is found to contain, of course, cells with nuclei and nucleoli of a particular character. Tumors of this kind are capable of acquiring considerable bulk, as the size of the fist, or a small head. They are slow in their formation, attended with more or less pain, and more or less numbness in the distal portion of the extremity, when the development occurs in one of the limbs.

Tumors of this description should be allowed to remain unmolested, unless they are productive of much pain and inconvenience, when we are obliged to interfere; the proper plan being to cut down upon the tumor, and enucleate it, allowing the nerve fibres to retain, if possible, their integrity. If this be impracticable, we do not hesitate to cut out the tumor as we would any other, exsecting it very carefully, dividing the nerve above and below the tumor, a procedure which will be followed by a loss of function in the distal portion of the limb, and may lead to mortification, as in a case reported by Drs. Dalton and Hoffman of Ohio.

The other variety of nerve tumor is known under the name of the *Subcutaneous Painful Tubercle*, originally described by Petit, and afterwards more distinctly by Cheselden, in the last century. You observe a little spot immediately beneath the skin, which it lifts up, as it were. It is connected with the superficial nerves which run immediately beneath the skin. This tumor is liable to occur in various parts of the body. It is usually considered to be more frequent in the inferior than in the superior extremity, but such is not the result of my own observation, which is, that it is found most frequently about the upper extremity and shoulder. It may be single or multiple; sometimes there are eight or ten, or even twenty, in the same individual. It is always productive of exquisite pain of a neuralgic character. Even one solitary tumor of this kind, not larger, perhaps, than a pea, a filbert, or a small almond, will be sufficient to make the patient perfectly wretched in consequence of the severity and constancy of this pain. It is sharp and shooting, or dull and heavy, liable to be aggravated by changes of temperature, and other causes.

The proper remedy is excision.

Reports of Hospitals.

NEW YORK HOSPITAL.

FEMORAL ANEURISM CURED BY COMPRESSION.

Service of Dr. C. M. Allin. House Surgeon, Dr. Charles Washburn, who has furnished notes of the present case, which will be followed by another in which the same treatment was employed.

Peter L——, æt. 19, native of New York, burnisher, admitted Aug. 13, 1867. At half-past eight o'clock, on the morning of admission, the patient had received a stab in the right thigh, the incision being an inch and a quarter in length, three inches below Poupart's ligament, parallel with the femoral artery, and almost directly over it. At the time of the accident, profuse venous hæmorrhage had occurred, but ceased spontaneously. On admission the wound was perfectly clean, the pulse rather feeble and accelerated, the skin cool and moist.

The patient was put to bed, and the wound left open for about five hours, when, no hæmorrhage appearing, it was closed with sutures, and a compress was applied over it with moderate firmness. At 6.30 P.M. the hæmorrhage recurred. On removal of the compress and sutures, the limb was found very much swollen, and the tissues about the wound were infiltrated with blood, which was still rapidly welling up, mostly venous, with a slight arterial admixture. The wound was enlarged, and an attempt made to find the bleeding vessel, but unsuccessfully. The femoral being uninjured, the artery wounded was probably the deep external pudic. A conical compress was placed in the wound, and completely arrested the hæmorrhage from both artery and vein. It was held in position by a Signorini tourniquet, which at 9 o'clock the next morning was removed, leaving the compress undisturbed. Two days later this also was removed; and the wound, now beginning to discharge, was syringed out with liq. sodæ chlor., its edges were slightly approximated by adhesive strips, and a dressing of lint and simple cerate was applied.

On the 18th the wound was filling up with healthy granulations. Above it, and to the inner side, was to be felt a decided induration, to which a pulsation was communicated. On the 20th the pulsation was more distinct, the hand perceiving a lifting sensation with each beat; and a single systolic *bruit* could be heard. All pulsation was arrested by compression of the femoral at the brim of the pelvis. The tumor was very much diffused, and its margins were not well defined. The point of most marked pulsation was situated 2½ inches below Poupart's ligament and 1½ inch to the inner side of the sartorius. The next day, the limits of the tumor were becoming sharper, and the *bruit* was more distinct. Pressure would empty the sac, which refilled by successive pulsations. The thigh was somewhat increased in size, but no part of the limb was œdematous. The patient beginning to complain of

severe neuralgic pains about the tumor and extending down the thigh, a hypodermic injection of 15 drops of Magendie's solution was administered at night.—Aug. 24th. A consultation was called at which Drs. Allin and Krackowizer were present. The tumor was still increasing in size, was now quite circumscribed, and about 3½ inches in diameter. Circumference of thigh over tumor 20½ inches, that of opposite thigh at same point 18 inches. No diminution in force of the tibial arteries. Inguinal glands enlarged and very tender. It was decided to employ compression of the femoral just below Poupart's ligament.

Aug. 25th.—Compression was commenced at 4 P.M. A Signorini tourniquet was used, modified by affixing a broad pad to the lower limb of the instrument, while the upper pad was made quite thick, in the shape of an inverted conic frustum. This was brought down so as but partially to occlude the artery, leaving pulsation in the tumor barely perceptible. The pressure was well borne until 10 o'clock that evening, when the patient began to have great pain at the point of compression, though that about the tumor and in the thigh had quite disappeared. The tourniquet was slightly loosened, and half a grain of morphiæ sulph. exhibited hypodermically. This induced a sound sleep, during which the instrument was again tightened. The patient remained comfortable, and the pressure was steadily maintained until the 28th, producing no œdema, or change of temperature in the limb. The chief embarrassment arose from the enlarged and tender glands just below the point of pressure. The wound had begun to cicatrize. On remitting the pressure the pulsation in the aneurism was found to have somewhat diminished, while its walls had become thickened in a marked degree. Pressure was renewed so as almost completely to stop pulsation in the sac, though that in the artery below the pad was still distinct.

Aug. 29th.—At 5 P.M. compression was removed, when the tumor was found perfectly consolidated, and all pulsation in it had ceased. The pulse in the femoral retained its normal force and freedom. The skin under the pad was uninjured. The apparatus was left loosely in place until next morning, 30th, when it was removed. The tumor then gave to the fingers a sensation of almost stony hardness. The thigh at this point measured 20 inches. The patient was free from pain, and very comfortable; had slept well, without an anodyne, since the 28th. The wound had nearly healed. On the 5th of September the patient was out of bed; the tumor softening; thigh measuring 19 inches. The case progressed favorably, and on the 16th September, the wound having fully healed, the patient was discharged cured.

OPERATIONS UPON PATIENTS WITH HEART DISEASE.—Mr. Paget, *Lancet*, does not believe that operations upon persons with heart disease are on the whole attended with a great deal of danger, and he affirms that the risk of chloroform is far less than the shock of the operation. Mere irregularity of the pulse, if it does not depend upon valvular disease or fatty degeneration of the heart, does not affect materially the chances of recovery.

CHLORATE OF POTASH INJECTIONS IN VESICAL CATARRH.—Vesical catarrh of a year's standing has been cured (*Southern Jour. Med. Sciences*), by injecting the bladder daily with four to six ounces of solution of chlorate of potash, one drachm to eight ounces of water, retained half an hour to an hour. The patient was a female, who had suffered greatly from the disease.

Progress of Medical Science.

INFLUENCE OF OPERATIONS UPON THE NERVOUS.—Let me tell you of the people that are commonly called "nervous." I do not refer to those with manifest disease in any part of their nervous system, but to those that are exceedingly sensitive, mobile, and excitable, whether in their sensitive or motor organs—who are very emotional, and with their whole cerebro-spinal nervous system altogether too alert. You will find them and their friends always apprehensive of the results of operations: they will tell you that they are so nervous they can bear no shock; and they look with the greatest apprehension upon the infliction of any injury. All this is fallacious. You may be surprised at observing how very little influence upon their organic processes this excessive vivacity of their cerebro-spinal system exercises. Time after time I have found patients who have complained of agonies in their wounds, and I do not doubt have felt them, but whose pulses have been unmoved. They have had enormous pain, but no fever, no single sign of disturbance of their general nutrition; they have had spasmodic movements of their limbs, tremblings, and rigors, but no mischief has followed. Besides, the same mobility of mind which makes these patients very fearful before an operation, makes them hopeful directly after it; and amongst all the people that can in any sense be called invalids, I know none who more generally pass through the consequences of operations with impunity than do those who are commonly called nervous, and whose nervousness consists, if I may use the expression, in too great a vivacity of their whole cerebro-spinal system.—JAMES PAGET, F.R.S., *Lancet*.

INCOMPATIBILITY OF POT. IODID. AND POTASS. CHLORAT.—This is an important point in practice, for in syphilis, to act at the same time upon the ulceration of the mouth and the general malady, chlorat. potass. and pot. iodid. are frequently given. This practice is dangerous, as has been demonstrated by M. Vée; for the chlorate of potash, absorbed simultaneously with the iodide of potassium, may part with its oxygen, and transform it into the iodate, a poisonous agent. The recent experience of M. Melsens proves the possibility of this transformation.

This ought to suffice to prevent, were it only as a precautionary measure, the simultaneous administration of the chlorate of potash and the iodide of potassium.—*Gazette Méd. de Paris*.

RESECTIONS.—M. Sedillot has written a letter to the Imperial Society of Surgery, on the regeneration of bone. It is too long for quotation entire, but of great interest. He contradicts the two principles of sub-periosteal resection in the following terms:

One, to which Larghi has given the general name of sub-periosteal resection, is founded on the idea that the periosteum detached and isolated in the condition of a sheath or a flap, is able to renew or reproduce the subjacent bone from which it is stripped or raised.

The other principle, which I have called sub-periosteal gouging or scraping, has for its principle, that it is the periosteum, *only when attached* to the bone, that is able to renew it; and that, in consequence, the bone beneath the periosteum should be husbanded and preserved with the very greatest care,

After invoking the aid of the Baconian method of research, M. Sedillot quotes numerous series of experiments which, in his opinion, are sufficient to prove that the periosteal flaps, if completely isolated from the sub-

jacent bone, are unable to reproduce it; "and that the so-called method of sub-periosteal resection is founded on a deplorable illusion;" and gives his opinion that the chief use of preserving the periosteum at all, is to supply a mould for the bony matter which is left in his method of periosteal gouging, and which really reproduces the bone.—*Ed. Med. Journ.*, *Gazette des Hôpitaux*,—*Am. Jour. Med. Sciences.*

Treatment of Croup.—In a memoir addressed to the Academy of Sciences at Paris on the subject of croup, Dr. Abeille sums up his conclusions concerning this disease, as follows:

1st. Croup is only a predominant localization of a general disease, diphtheria, and only in some exceptional cases can it be met with as a local disease.

2d. Local treatment alone is powerless to arrest croup, and can only fulfil an indication, which is, to combat its localization, and in this respect such a mode of treatment is very proper, providing it does not complicate the existing symptoms; such, however, may be the effect of cauterizations of any kind.

3d. Croup often kills by asphyxia; it terminates fatally frequently when there exists a pseudo-membranous affection of the bronchial tubes and lungs, or when there is a general infection of the system, which may in some manner be compared to putrid infection. Tracheotomy, performed solely to prevent the patient dying from asphyxia, while the diphtheritic exudation may disappear spontaneously, or be removed later by local or general treatment, is the practice generally adopted at the present time, but is not justified either by results or scientific deductions. The results officially known during a period of six years and a half at the hospital "Sainte Eugénie," and which should not differ from those of other hospitals during the same lapse of time, show three deaths out of every four patients upon whom tracheotomy was practised. During the time of Rosen, with the treatment which is considered detestable at the present day, the mortality did not exceed a third of the cases operated, and if we add to the cases of croup operated at the "Sainte Eugénie," those receiving medical treatment only, we find a third resulting in death, precisely as during the time of Rosen; that is to say, that, as a general result, tracheotomy has added nothing favorable to the treatment of this disease (Statistics of M. Bourdillat read before the Society of the Hospitals, 26th of July).

4th. It is then positively proved that it is from a medical treatment, capable of combating the disease both in its general and local predominant manifestations, that science should seek to arrest the progress of croup. This treatment, says Dr. Abeille, from our own efforts, which were crowned with success in exceptionally bad cases, and for a stronger reason in cases less serious and relatively benign, may be summed up in the three following propositions, two of which are currently accepted in practice, and the third one, which is of recent introduction, is the inhalation of moist vapors of the sulphide of mercury, a suitable diet, and the free use of emetics.—*Gazette Médicale*, Nos. 37, 38 and 39.

Iodine Inhalation in Diphtheria.—Mr. J. Waring Curran (*Lancet*) extols the inhalation of iodine in diphtheria, and claims for it the property of arresting the development of the membrane. He thus speaks of its employment:

The formula which I employ for inhalation purposes is the same as that formerly used by Sir Charles Scudamore in pulmonary phthisis—viz.: Iodine, iodide of potassium, of each four grains; alcohol, four drachms; water, four ounces. Of this, for each inhalation, commencing, I take a drachm; add to it a pint of vinegar infused with a handful of dried garden sage, placed in a common inhaling jar, steadily increasing the quantity of iodine solution until I arrive at half an ounce each inhalation. The circumstances of the case, the age and strength of the patient, and the severity or mildness of the attack, guide me with regard to the number of inhalations, and the time occupied by each. For an average case, occurring in a healthy patient, I would say twelve inhalations at least per diem, with eight to twelve minutes (an interval allowed to rest) for each. The loss of valuable time in country practice, occasionally, will not permit the delay of sending and waiting for an apparatus; accordingly not unfrequently I have been compelled to make my inhalation in the following manner: Having boiled the vinegar and sage, place it in a teapot with a long spout, and when the patient is prepared to inhale, add the iodine, cover the lid of the vessel with a cloth, keep up the temperature by a spirit-lamp placed underneath, and holding the vessel by the handle, allow the patient to inhale through the spout. Laryngeal irritation is in a great measure prevented by the small quantity at first used, through the patient becoming gradually accustomed to it.

Prompt Action of Turpentine in the Treatment of Tænia Solium. By M. A. McClelland, M.D., Knoxville, Ill.—I was summoned at 4 o'clock P. M., Nov. 19, to see a patient, at the depot, who was in a "fit." Learned from the bystanders that the young man had fallen suddenly forward on his face, and for a few minutes had severe spasms, with frothing at the mouth. In the fall he injured his nose sufficiently to cause considerable hæmorrhage. Found him in a semi-stupor, breathing easily, pupils responding to the light. In a few minutes he recovered sufficiently to inform me that he was very tired, and that he had had these "fits" before. By this time his father had arrived, from whom I learned that the patient was twenty years old, and had been generally healthy—had usually a voracious appetite, and that three years before he had passed a great many worms, and at one time a portion of what was supposed to be a tape-worm six feet long. With this evidence I diagnosed the case "epileptiform convulsions," depending on Tænia. While lying on his back the hæmorrhage from the nose took place into the throat and was swallowed, and, as it was causing the patient to vomit, I deferred treatment till morning. At 6 o'clock A. M., Nov. 20, I began to exhibit tablespoonful doses of ℞ Turpentine ℥jv., Mucilage Gum Acacia ℥ij., Syr. Simp. ℥ij., Ess. Lemon ℥ss., every half hour. At 9 o'clock A. M. saw the patient, who was tolerating the medicine well, and ordered two tablespoonfuls at a dose. The patient, on his own responsibility, made it three. At half-past 10 A. M., he came marching, highly elated, to the office with the parasite carefully wrapped up in a paper. The worm came *en masse*. Did not learn from patient whether it showed signs of life or not. The neck of the worm was tied in several knots, which I feared to undo lest I should break it. Measured carefully it gave nine feet, which, with the six feet passed three years before, gave an aggregate of fifteen feet, which is the average length. The bowels had been constipated for a long time. The emulsion caused active catharsis, and with a rapidity my experience would not have led me to anticipate. The above case exemplifies the therapeutic value of Turpentine, given in large doses, in the treatment of Tænia. The only ill effect has been a moderate strangury, which is readily yielding to flax-seed tea.

Poisoning by Sumach.—Dr. Braman (*Med. and Surg. Reporter*) recommends local application of dry calomel or citrine ointment not only for sumach but ivy poisoning.

THE MEDICAL RECORD.

SPECIALISM AND GENERAL MEDICINE.

THERE is no doubting the fact that the study of special branches, as now carried on, is rapidly enlarging the domain of medicine. The specialists, so called, despite any prejudices that may exist in the minds of the general practitioner concerning temptations to magnify the claims of respective departments, must be considered as benefactors of their craft. As such they should deserve the thanks of every one who is a friend to science and an advocate for progress. All who have watched the advances which specialism has made, and have noted the number of able men who have been coaxed into special studies, must admit that its claims to respectable recognition are pretty well established. There have been very few who would be willing to deny any good results which might grow out of the study of a specialty: the difficulty, however, has been to settle upon the proper relations which should be maintained between specialism proper and general practice. We are well aware that extreme sides have been taken on this point, and that the present unsettled state of the question has been the natural result. The general conviction which forces itself upon every one who has examined into the respective merits of the case is that the whole difficulty rests upon the want of a proper understanding between the two parties. The subject, viewed in the broad light of common sense, admits of an examination, the results of which can be mutually satisfactory.

The respective positions of general practitioner and specialist are, in truth, very different from each other. The former is the proper medium of communication between the people and the profession; while the latter is, strictly speaking, separated from the people by the profession. To the practising physician the general public naturally look as the only one who is supposed to be acquainted with their ailments, and who is able to give suitable advice. The specialist, however, depends almost solely for patronage upon the recommendation of his brother; he dares not, unless he wishes to dishonor himself and his calling, bring himself and his qualifications more directly to the notice of his patients. He is forced to throw himself wholly on the generosity of his endorser, and it is of the utmost importance that his delicate position should be properly appreciated by all parties concerned. A specialist becomes such after a very long and patient study of a particular branch in medicine, and if at the end he is not privileged to enjoy the fruits of his labors by the generous countenance of his confrères it is an injustice not only to him but to the science of medicine at large. We are, perhaps, ready to say that the specialist is an extremist, that he is one of a class who see only one subject for study, and that his habits of thought will not allow him to travel outside of the path which he has marked out. Although this may be true of some, it is by no means the case with the majority; the true specialist, to our mind, is one who is well enough grounded in the general principles of medicine to guard him against such an error. The determination to unravel difficult problems and to work properly in a good cause is manifest in most of his doings; and even though we are ever ready to condemn transcendentalism, we should be equally generous to overlook its commission in the surety that in it are buried many important, valuable, and indispensable truths, which otherwise would never have been elaborated.

The specialist differs from the ordinary physician in that he has prepared himself from practice in the most difficult cases that may occur in a particular branch. This difference is becoming more and more appreciable as the study of specialties is advancing and enlarging its area. It is preposterous for any one to suppose, however powerful may be his intellect, however apt at gaining information, however skilful as a manipulator, that he can be a specialist in every branch. Even the most obstinate opposer of specialism will not be prepared to allow the possibility of such a state of things. Some men, it is true, have made an approach toward the accomplishment of such an end, but it has, after all, been only an approach. We are not only forced to acknowledge the benefits of specialism in theory, but the general practitioner must apply the theory to practice; he must not only admit that specialism is necessary to the advance of our knowledge in different directions, but must be prepared to support those who labor in the cause of its advancement. This he can very well do by taking an honest view of the position of things, and can thereby advance both his own and his brother's interest.

We are not as yet inclined to draw a line of rigid distinction between the two classes of practitioners, but are convinced that the time is not far distant when the necessities of such a course will be apparent to the most conservative. At present we are in just this position, and should be prepared to act in accordance with its demands:—The general practitioner, if he desires to be a type of his class, a model family physician, so to speak, can hardly expect to be much of a specialist in any department except, perhaps, midwifery. He must take the pains to fit himself for all the ordinary cases that may come to him; and these, we may say

in passing, are sufficiently numerous and important to engross all his thoughts and direct all his energies. He can certainly make himself as useful in such a line of duty, and accomplish as much good as can the specialist, who has a smaller and perhaps more cultivated field to work in. General medicine overlaps specialism sufficiently far to gratify the ambition of any ordinary conscientious practitioner. This common ground, so to speak, embraces the elementary departments of all specialties, and is as much the province of one class as the other. While the specialist is expected to be thoroughly grounded in the elementary as well as the more advanced part of his branch, the physician must know how far he dare go in the treatment of any of the organs now specially studied without the aid and advice of an expert. His position, after all, is the most enviable of the two; he has more variety in his practice, has an opportunity, to a certain extent, to avail himself of the various new ideas which are presented to him, and to choose the most eminent men in all special departments for counsel. An enthusiastic specialist has likened the profession generally to the rank and file, while he pleases to call the experts the leaders. Can we not, however, for the sake of an illustration of our idea, turn the tables? If we begged to differ with him in his particular view of the case, we would liken the practitioner proper to the general who, when he is about to fight a battle, calls around him his staff, counsels with them, and combines the views of all in a plan of his own.

The report of the case of extirpation of the uterus, by Dr. Hackenberg, in the present number, will be of interest to our readers, not only in itself, but as the representative of a class of very important, severe, difficult, and fatal operations. The uterus was first removed during life through the abdominal walls, twenty-one years ago, and up to Sept., 1865, forty-two cases have been recorded, with eight cures. Since that time the list of operations has been increased by six; one by Wood, of Cincinnati, one by Sands, and one by Krackowizer, of this city, the one in the present issue, one by Atlee, reported at a recent meeting of the N. Y. Pathological Society by Dr. E. Delafield, and one which has not yet been published, by Weber, of Cleveland. All of these latter terminated disastrously, so that the ratio of good results has decreased from eight in forty-two to eight in forty-eight. This is indeed a frightful mortality, and, when we compare the results with its sister operation, ovariotomy, there is, surgically speaking, a wide gap between them.

The lesson which every practitioner should be willing to learn from Dr. Hackenberg's case is that which relates to the necessity of a correct diagnosis to begin with. The mistake which is so candidly stated has not been committed by him alone, but by many others who have preceded him. Indeed, the majority of the operations which have been performed have been based upon just such an error. It is not likely that the same thing will occur again with the same individual, but then experience should be a wholesome warning to others to "make assurance doubly sure" before trusting the patient to the meagre chances of success which the operation offers.

We would take occasion to state that the delay in the appearance of our last number was unavoidably occasioned by the issue of an extraordinarily large edition.

Reviews and Notices of Books.

Synopsis of the Course of Lectures on Materia Medica and Pharmacy, delivered in the University of Pennsylvania, with Five Lectures on the Modus Operandi of Medicines. By Joseph Carson, M.D. Fourth edition, revised. Phila.: H. C. Lea. 1867. Pp. 272.

As the title of this little work indicates, it is a mere synopsis of a course of lectures on materia medica, delivered at the University of Pennsylvania, and is calculated almost solely for the use of the students of that institution. As such it doubtless subserves its purpose, but there are too many points referred to in the text, which require elucidation in the lecture-room, to recommend it to the students of medicine generally. There are, however, contained in the work five excellent lectures on the modus operandi of medicines, which, by themselves, cannot be excelled for systematic arrangement and sound reasoning.

A Dictionary of Medical Terminology, Dental Surgery, and the Collateral Sciences, by Chapin A. Harris, M.D., D.D.S., Professor of the Principles of Dental Surgery in the Baltimore Medical College, etc. Third edition. Carefully revised and enlarged by Ferdinand J. S. Gorgas, M.D., D.D.S., Prof. of Dental Surgery in the Baltimore College, and Vice-President of the Association of the Colleges of Dentistry. Phila.: Lindsay & Blakiston, 1867. 8vo, pp. 743.

Owing to the much lamented death of Prof. Harris, his dictionary did not advance to a new edition as rapidly as the requirements of the case demanded. The many advances in dental science, which have been made during the past few years, have rendered the incorporation of many new terms and formulæ absolutely necessary to the student of dentistry, as well as to the dental practitioner, and they especially will be gratified to learn that the task of the present editor has been conscientiously and satisfactorily performed. Nearly three thousand new words have been incorporated into this edition, besides additions and corrections to many others. A noticeable feature of the present edition is the mention of the doses of the more prominent medicinal substances. As a work for reference to those studying or practising dentistry, it is in our opinion invaluable. The arrangement and concise treatment are everything that can be desired, and the work as a whole is what its title indicates. It is beautifully printed, and, as far as we can be able to say from a cursory review of its contents, free from typographical errors.

Photographs of Skin Diseases, taken from Life, under the Superintendence of Howard F. Damon, A.M., M.D., Fellow of Mass. Medical Society, etc., etc., etc. Boston: 1867.

We are always interested in every attempt to elucidate, and thus facilitate the study of any branch of disease, and more especially of one which is too often so dis-

couraging to the busy practitioner as that of cutaneous diseases; and therefore welcome this enterprise of Dr. Damon, the first ever attempted in our country, to press photography into this service. Colored photographs and chromo-lithographs have already been used for this purpose; but they fail in giving a correct idea of these affections, unless made too expensive for the student. Dr. Damon, therefore, leaves his plates uncolored, and is thus able to give a more correct idea of the form, arrangement, etc., of them.

Dr. D. proposes to issue these photographs in four series, each to consist of six illustrations, making twenty-four plates in all; and, if patronized by the profession, to continue them until a complete atlas of these diseases is presented. Two plates are to be issued each month, the series to be completed in about a year. They have been taken by artists employed for the purpose, from selected cases under his observation in dispensary, hospital, and private practice.

The first two plates of this series, which we have received, represent chronic eczema of the hand and herpes zoster, and are fine specimens of art; and we trust that the enterprise will receive the encouragement which it merits.

"EPIDEMIC MENINGITIS OR CEREBRO-SPINAL MENINGITIS." By ALFRED STILLÉ, M.D., Professor of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania, etc., etc. Lindsay & Blakiston, Philadelphia. Pp. 178.

DURING the epidemic of cerebro-spinal meningitis, which has existed in the United States for the past ten or eleven years, so much has appeared in the different medical journals in regard to its nature, treatment, etc., that there seems little space for anything very new. In accordance with this, the present work seems rather a resumé of what has been said. It contains nothing particularly new; but the observations and opinions of many different writers *are brought together, compared, and criticised.* The present work is well suited *for those who are anxious to find in one book all that has been said on the subject,* while its complete bibliography shows the more curious reader where to look for more minute information.

The authors consulted are American, English, Irish, French, German, etc.; and reference is made to about all of the epidemics that have been reported. In some places the author seems to have adopted German ideas, and along with them a German mode of expression. But this would only be another instance of the difficulty of separating the two; when an idea has been fully developed in German, it seems to rebel against being clad in pure English.

The symptoms furnished by the nervous system, organs of the senses, digestive organs, urinary organs, pulse, skin, etc., are separately considered. And we are very happy to see the explanation of the *causes* of so many of the different symptoms given. In many medical works we find a bare enumeration of headache, deafness, constipation, etc., which symptoms taken together are said to form a disease. But no explanation is given *why* the symptoms arise. After reading over the list, we must carefully study out for ourselves each component of the disease. It is so generally considered the duty of the physician to treat *symptoms* that it becomes important for him to know *how* to do so. This knowledge can only be certainly acquired by becoming acquainted with the cause. For instance, while in scarlatina the deafness will depend on the throat-trouble or an extension of it, in cerebro-spinal meningitis "this symptom appears to depend chiefly upon the pressure of the plastic exudation in which the auditory nerves are embedded." Of course if treatment were directed to this symptom, it would necessarily be different in the two cases.

Until the immediate causes of all the symptoms of a disease are known, we cannot expect to know its *ultimate* cause.

The cause of cerebro-spinal meningitis appears involved in as great obscurity as ever. It seems determined that it is *not contagious.* But while this negative point is settled, there seems to be nothing new on the positive side of the question.

After discussing the positive diagnosis, the comparative diagnosis between this disease and hysteria, typhoid and typhus fevers, is extensively argued.

The article on treatment we regard as very practical and sound; ice to the scalp during the continuance of pain in the head, blisters to the scalp and nape of the neck are recommended. Alcoholic stimulants are not to be used until required. Opium is highly spoken of: "Among the symptoms which it was particularly intended to relieve, was one which is usually thought to be increased by narcotics, viz., coma." Quinine is considered as being only useful as a tonic. The benefit of mercury is doubted.

This essay is very interesting, as containing all that is at present known of this very curious disease, and will prove an excellent starting-point for future observations.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

CALLED MEETING, DECEMBER 19, 1867.

DR. HENRY D. BULKLEY, Vice-President, in the Chair.

A NEW METHOD OF TREATING THE OVARIAN STUMP AFTER EXCISION.

DR. HORATIO R. STORER, of Boston, Mass., read a paper upon the above subject, in the course of which he recited the case of a patient, a lady from Columbia, Tenn., from whom he had removed an unilocular cyst of left ovary, in Chelsea, Mass., September 23, 1867. There were present, Mr. T. Spencer Wells, of London, Eng., Drs. Kimball, of Lowell, Lincoln, of Boston, and Wheeler, of Chelsea. The tumor, with its contents—a straw-colored albuminous fluid—weighed forty-three pounds. A portion of the fluid, however, had been allowed to escape through a puncture made by a trocar with a tubing attachment. The pedicle, which was about the size of the thumb, was divided by the scissors, after the application of Dr. Storer's clamp shield.* When the clamp was relaxed, but one artery of moderate size required ligation, which was effected by iron wire. The walls of the primary incision were brought together by twenty iron-wire sutures; the end of the pedicle was brought between the inner lips of the wound at its lower angle, where it was "pocketed." "Pocketing the pedicle," as he (Dr. Storer) proposes to designate it, is effected by passing three of the stitches through the pedicle and both inner edges of the abdominal wound, after which the external edges are brought together. This procedure coaptates the raw surfaces of the wound with the raw surface of the pedicle, while the line of superficial union completely covers over the whole.

The operation was performed during menstruation, to which fact Dr. Storer especially directed attention, as being a deviation from the general practice. This

*For description of this instrument, see *Medical Record*, vol. i, p. 885.

period, he did not think, was necessarily dangerous. Furthermore, the shock of the operation, and the removal of one ovary during menstruation, had no appreciable effect upon the amount of the catamenial discharge. The accepted views of the profession in regard to the essential character of menstruation, he thought required modification. He alluded to a case in which he had successfully removed the uterus and both ovaries,* where there was a sanguineous effusion eighteen days after the operation, and twenty-six after the last catamenia. The lady alluded to, he would state as a matter of some interest, was still in perfect health.

Dr. Storer also gave the details of a case in which both ovaries had been removed, and in which the pedicle had been treated somewhat differently from the usual method. He had, instead of dividing the pedicle, dissected away from the encompassing masses the Fallopian tubes throughout their entire length. The peritoneal wounds were closed by wires, which served the purposes of both ligatures and sutures: five of these being inserted upon one of the tubes, and three upon the other. This patient, who made a very good recovery, has had, since the operation, quite regularly a sanguineous discharge, not referable to any disease of the uterus, and not under the control of any hæmostatic. This, too, in its persistence, is quite different from the hæmorrhagic discharge following hard upon an ovarian section.

Another notable point in the first operation, as related in the paper, consisted in the novel way of treating the stump, in alluding to which Dr. Storer maintained that the knife was objectionable, on account of the hæmorrhage so apt to follow an incised wound, and the liability of a free and fatal flow from the slipping of the ligatures.

The écraseur also had its disadvantages, one of which was, when his clamp shield was not applied, that of dragging in outlying tissues, and thereby increasing the number of divided vessels. Besides, too, a contused wound is apt to give rise to a more profuse suppuration.

The cautery, says Mr. Wells, "would almost certainly fail to stop such large vessels as are frequently met with in a pedicle." Mr. Baker Brown's testimony in its favor is to be received with due allowance. His own method of dissecting the Fallopian tubes away from the diseased mass, as practised in the first related case, has for its recommendation: 1st. No unnecessary division of vessels. 2d. A probable primary union of the cut peritoneal surfaces along the Fallopian tubes. 3d. The avoidance of hæmorrhage; and 4th, the absence of contact between any general peritoneal surface, and any newly divided or suppurative tissue.

In this way the serous lips of a peritoneal wound may be approximated and mechanically made to close the mouths of bleeding vessels. In the case of a long pedicle, the second method is usually practicable. The stump should be "pocketed." When short, or where there is practically none at all, the stump can still be "capped." Metallic sutures are to be preferred. Dr. Storer then took up the topic of subsequent treatment of the stump. He remarked that whether the stump was *intra-mural* or *extra-mural*, there were certain serious dangers to be considered. The *intra-mural* attachment, or "pocketing," was intended to obviate these. Mr. Hutchinson, when he brought the extremity of the pedicle outside of the abdominal wall, lessened the mortality very much, since he decreased the risk of hæmorrhage, of peritonitis, and of a subsequent hæmatocele, from reflux of the catamenia through the divided Fallopian tubes—a frequent accident, liable to end fatally. He allowed that the external method (whether by clamp, pins, or sutures) is, where the pedicle is long enough, far superior to the wholly internal method. But he agreed with Mr. Wells that it was not yet perfect, and quoted from that ovariotomist several objections.

He claimed that by "pocketing" many difficulties were overcome, as for example the most favorable condition for primary union was obtained in that two raw surfaces were brought directly together; hæmorrhage, either primary or secondary, was as easily prevented as when the stump was external; there was no inevitable fœtid discharge from the stump; when there had been a careful adaptation of surfaces, there was slight risk of exciting suppuration in adjacent tissues. The existence of an infra-umbilical uterine outlet for the catamenial flux, and the occurrence of an intra-peritoneal hæmatocele, were rendered impossible, while traction upon, or strangulation of intestine, was quite unlikely to happen.

After an allusion to certain prospective modifications in some of the minor details of the operation, Dr. Storer gave as a reason for his having made the attachment at so high a point, viz.: midway between the umbilicus and the pubes—a desire to provide against any subsequent pregnancy by allowing the uterus to rise to a higher point.

Dr. Storer, during the reading of his paper, remarked *ex tempore* upon Dr. Krackowizer's case of extirpation of the uterus by mistake for ovarian tumor.* He maintained that an absolutely certain diagnosis in that case, as indeed in many other such, was not only nearly but quite impossible of attainment.

Dr. Peaslee said: He was very much interested in the paper read by Dr. Storer, which he considered a progressive one. Dr. Storer's method of treating the pedicle in ovariotomy may also be proved by experience to be the best method. But up to the present time he, Dr. P., thought the best way to treat the pedicle is to tie it with a double silk ligature, passed through its middle—each half of the ligature inclosing half of the pedicle—then to cut the ligature close to the pedicle, and let the latter remain in situ in the abdominal cavity. Thus the abdominal incision may be completely closed at once. He did not mean to say he would adopt this method in every possible case, but he thought it altogether superior to any other of all the methods hitherto used and specified by Dr. Storer. In patients, however, like Dr. Storer's, with a monocystic tumor, without adhesion, and with the other favorable conditions specified, Dr. S. would probably have succeeded in nine cases out of ten, and perhaps nineteen out of twenty, whichsoever of the commonly approved methods of treating the pedicle had been adopted. The operation itself in such cases is facile, and no special care in after treatment is required. On the other hand, cases of polycystic tumors, with extensive adhesions and unfavorable conditions of general health, will too often prove unsuccessful, however the pedicle may be managed.

Still, the management of the pedicle is doubtless an important element of success, or the contrary, in the less desirable cases, and deserves consideration in every instance. He was very positive, too, that the success of ovariotomy had been greater in proportion to the number of cases, when the pedicle had been treated according to the plan recommended by himself. Dr. Tyler Smith, who operates in this way, saved eleven out

* *Medical Record*, vol. i., p. 168.

* Vide *Medical Record*, Sept. 1, 1867, p. 297.

of fourteen patients; while Mr. Bryant* saved only ten out of his first nineteen cases, in which, with four exceptions, the pedicle had been treated by other methods, but of his last seven cases treated in the way he was commending, *all* recovered. The whole number of cases treated thus far in this way is, however, still small, compared with those treated with the clamp, and by the ligature (Clay's method) left hanging out through the abdominal incision—the method he adopted in his first operations, and which he still preferred to all others, except the one he now advised.

It has been objected to the method which he preferred, that a slough of the stump was sure to occur beyond the ligature, and that this decomposed mass, falling into the peritoneal cavity, would become absorbed and produce septicæmia. In corroboration of this view, Dr. Routh's experiment of placing a piece of flesh, while still fresh, in the peritoneal cavity of one of the lower animals is cited; since here, it will be remembered that the flesh underwent decomposition, and produced fever of a low type from absorption of the septic fluid. Mr. Spencer Wells, indeed, suggests on this belief, that the ligatures, if used at all, had better be brought out through the abdominal incision, in order to draw off the decomposed fluid in the peritoneal cavity by capillary attraction.

Now, in reply to this objection, Dr. P. would say:

1st. No symptoms of septicæmia, and no fever of a low type had occurred in the cases treated as he had recommended; which shows that no such sloughing of the pedicle, as is invoked by the opponents of this method, takes place. It may *possibly* occur in exceptional cases; but as a general proposition, he must infer that it does not, and that Dr. Routh's experiment therefore directly favors this method, instead of being opposed to it.

2d. He (Dr. P.) has had *the fact* demonstrated in three cases, in which six ligatures were applied, that no slough of the extremity of the pedicle occurs. Two of the patients died on the seventeenth day, and the third (not his own case) a few days earlier. Of the six masses inclosed, not one had sloughed. All were connected with the adjacent surfaces by an exudation which had maintained their vitality, though some of them were now completely cut off by the ligatures; and neither of the three patients had had any symptoms referable to the pedicle at all.

He knew of no other objection of any weight to the method he proposed.

On the other hand, this procedure admits of a complete and immediate closure of the abdominal incision, which is of course expected to heal by first intention. Besides, the ligature is the surest safeguard against *hæmorrhage* that is known, and the one always adopted when the other methods fail to arrest it. He had seen not a few instances in which the clamp, the actual cautery, the silkworm's intestine, or the silver wire, failed to control the hæmorrhage from the pedicle, and it was necessary to resort to the ligature at last. It seemed to him in all these cases that it would have been quite as wise if it had been used at first, without so much manipulation and loss of time. Any means of arresting hæmorrhage *may* fail; but he had applied, and seen applied, not less than forty ligatures to pedicles without the occurrence of hæmorrhage in a single instance. And in those cases in which the ligature had slipped off of the pedicle, only a single ligature had been passed round the latter, and then the pedicle also had sometimes been cut too close to the ligature.

This is a method also which may be applied to all cases, and is the only one for very short pedicles (unless the cautery or the écraseur be preferred). Of course the method of Dr. Clay is also applicable to all cases; but he supposed that if the ligature is to be used at all, none would prefer to have the ends coming out through the abdominal incision, provided there is no sloughing matter to be brought through in that way, and that the loops remaining behind produce no mischief, as is known to be the fact. Dr. Peaslee had had septicæmia occur in three of his cases, but not from any agency of the pedicle in either instance. These three cases recovered.

On the contrary, Dr. Peaslee regarded the fixing the pedicle in contact with the abdominal walls in any way, whether by sutures or the clamp, or by "pocketing," as proposed by Dr. Storer, as very objectionable. Fortunately this could not be done if the pedicle was very short; but the probability that such an adhesion would interfere with the upward development of a gravid uterus is very great, although parturition has followed in a few such instances. And Mr. Wells has reported a case of death from strangulation of the intestines by the band thus extending across the peritoneal cavity. Why not so manage the pedicle that if the patient survives the operation the recovery is perfect?

Still, ovariotomy is an operation in regard to which, more than any other perhaps, we should guard against exclusive views. Experience will perhaps show that one method of treating the pedicle is better in one class of cases, and another in another class. Meanwhile he adheres to the one as generally best, which he thought had thus far succeeded proportionally better than any other; and which presents, at the same time, certain advantages not secured by the maintenance of the pedicle in contact with the abdominal walls, and avoids the inconveniences also which that method involves. In regard to the other points in ovariotomy also, we must have no preconceived notions on commencing the particular operation; since if uncomplicated it is one of the simplest and easiest of surgical procedures, while in the most difficult cases it is the most formidable operation ever attempted. And with the exception of the class of cases already mentioned as strongly promising success, no one can tell before opening the abdominal cavity what complications he is to meet. The operation, therefore, should always be commenced as an explorative procedure, and with the understanding on the part of the patient and the friends, that it may fail of completion, should complications be found which render its completion the more dangerous course.

In regard to the removal of fibro-cystic tumors of the uterus, Dr. Peaslee remarked that he had not had so much experience as Dr. Storer, and that he had neither been so fortunate nor so unfortunate. He had removed two such tumors, one patient dying in forty-eight hours and the other at the end of a week. The latter, however, died actually of gangrene of the intestines, from hernia through the abdominal incision, produced by violent coughing; the post-mortem showing that she would doubtless have recovered from the operation so far as the uterus and its appendages were concerned.

In regard to the case reported by Dr. Krackowizer of mistake in diagnosis, Dr. Peaslee remarked that he thought no apology was required for it. He (Dr. Peaslee) had once made a similar mistake, after availing himself of the sound and all other recognized methods, he believed, of diagnosis; and he or any one else might do the same again, he thought. No physician ever pretends that he can always distinguish with certainty between two diseases, even when on the surface of the body; and any surgeon who expects always to be able to decide with unerring certainty between two or

* *London Lancet for August*, 1867, p. 513.

more kinds of tumors in the abdominal cavity, will not only sometimes find himself deceived if he pronounces positively, but he will also hold up to non-medical men a standard which they will not be slow to turn to the disadvantage of the profession generally. It is well to understand, and also to admit publicly even, that human diagnosis recognizes such a thing as an impossibility, and always will do so.

Dr. Emmet stated that his experience in ovariotomy had been limited to some half-a-dozen cases. As a matter of safety, he had been unable to make up his mind, in either of these cases, to drop the pedicle back within the abdomen. He had secured the pedicle crowded down in the lower angle of the wound, not with a clamp, but included in the abdominal sutures. In each he had carried out somewhat the same idea as proposed by Dr. Storer, with a view of covering early the stump of the pedicle. That he had been in the habit, after the fourth day, of cutting off the ligature around the stump and gradually removing the sutures, including the pedicle, before the others, so as to draw the edges of the abdominal wall over it. That this plan was a safe one, as the peritoneum united rapidly and firmly after twenty-four hours; as the stump was not entirely strangulated, he had never had any sloughing from the end. He was also convinced, when the pedicle was to be brought out of the lower angle of the wound, that the best plan to be adopted in regard to the incision was to make it as near down to the pubes as possible, that is, so far as was consistent with safety. In his cases no pregnancy had occurred; but he knew of one instance, in Dr. Sims' practice, where the pedicle was included in the lower angle of the abdominal section, and the patient had borne three or four children since without any difficulty, from this plan of treating it.

Dr. Noeggerath, after reviewing the additions to our knowledge of this subject, called attention to the fact that Dr. B. Stilling, of Cassel, was the first to propose (in 1837), the extra-peritoneal adjustment of the pedicle. His method consisted in tying the pedicle *en masse*, and uniting it by pins with the raw surfaces of the abdominal wall, leaving the section above the ligature outside in contact with the air; thus effecting only a partial union between the same and the integuments. Therefore Dr. Storer's manner of treating the pedicle was an original one in principle.

Dr. N. could not with Dr. Peaslee so strongly endorse the intra-peritoneal management of the stump. There were some rather serious objections to its application, among the chief of which was the unreliability of the ligature against the occurrence of hæmorrhage resulting from the shrinking of tissues, which were quite succulent when the ligature was applied. In this case the ligature would of course become loosened and no longer fulfil its office. He recalled a case of his own, upon which he had operated in October, 1866, and in which a double ligature, as tightly drawn as could be, became loosened in a few hours and originated an alarming hæmorrhage.

Another objection to Dr. Peaslee's method consisted in the possibility of the occurrence of sloughing of the stump and septic peritonitis from this cause. This accident could not occur when the cut surface is being surrounded by an exudation of lymph from that part of the peritoneum with which it comes in immediate contact. But in case the pedicle should happen to touch a peritoneal surface of low vitality, owing to continued pressure from the cyst or to repeated attacks of subacute inflammation during an earlier stage of the cystic development, why, then, gangrene is very apt to take place around the portion included within the ligature. How far decomposition *might* go on, Dr. N. had himself seen in one instance, where the tissues not only above but *below* the ligature came away to the extent of some three-fourths of an inch.

To Dr. Storer's enumeration of the different modes of treating the stump, two might be added, which he would proceed to mention. The first of these, adopted by Dr. Koeberle of Strasburg, consisted in severing the pedicle by a small wire écraseur, gradually tightened during a period of several days; after which everything was left in the abdominal cavity. The secretions were then washed out as they occurred.

The second plan was a proposition of Dr. N. himself, and consisted essentially in leading the pedicle through Douglass' space into the vagina, where it was to be secured. Thus being in sight, and out of harm's way, it could be more readily commanded in case of emergency. In recommendation of this, it was to be borne in mind that inflammation as well as lesions following the pelvic section of the peritoneum, seemed to be borne with less danger than those of other peritoneal regions; a fact fully corroborated as well by the general innocuity of perimetritic inflammations as by his own experience, since he had operated at least fourteen times, either by the trocar or the knife, for drawing ovarian cysts through the vagina, without losing a single patient from the effects of traumatic inflammation.

Dr. Peaslee, in reply to Dr. Noeggerath's remark respecting the increased amount of blood in the pedicle after the application of the ligature, and its subsequent diminution, thus producing a shrinking of the pedicle and a loosening, and perhaps the detachment of the ligature,—said he made issue with any one who might make that assertion. On the contrary, there being no further need of blood circulating through the artery of the pedicle, there was very little pressure of blood into the pedicle. So true is this, that in one of S. Wells' cases, there was no bleeding from the pedicle, though he removed the clamp (it produced such violent symptoms from dragging on the uterus) in *four hours* after it had been applied.

In regard to menstruation occurring after both ovaries had been removed, as in the cases quoted by Dr. Storer, Dr. P. would say, that he had removed both ovaries in three cases, and the patients are all now living. Neither of these patients has menstruated since the operation. He has in four cases seen a flow of blood from the vagina for three or four days, and commencing the third or fourth day after the operation. But he considered this as merely a hæmorrhage occurring in consequence of congestion of the uterus from the operation, and hailed it as a good omen, as that congestion was thus spontaneously relieved.

Dr. Storer did not wish to be understood as laying down any invariable rules, even for a given operative procedure, since too many probabilities were to be taken into account. But he did desire to put himself on record as one who was very strongly in favor of preparatory treatment, in the case of *all* abdominal sections, believing it to be much more rational to *prevent* than to *remedy* shock. He would prefer, for instance, to give stimulants before anæsthesia rather than when danger was imminent. So, too, owing to the present accepted practice of preparing the pregnant woman for her ordeal by a proper attention to her constitutional conditions, much suffering was saved, and not a few dangers averted. By preparatory treatment in the cases to which he had just alluded, he desired to be understood as meaning something extending ever a reasonable period of time. He believed, too, that to operate was one thing, but to conduct the case afterward quite another—indeed those who wearily watch

over the case, as he has himself had an opportunity of knowing, are, after all, entitled to the greater share of credit for the successful issue.

In response to the resolution of the Academy, asking for a copy of his paper for publication, Dr. Storer said that the same would appear in the *American Journal of Medical Science*, for January.

Dr. Anderson did not think that this fact would conflict with the resolution.

The resolution prevailed, and the Academy adjourned.

N. Y. MEDICAL JOURNAL ASSOCIATION.

Stated Reunion, Friday, December 6, 1867.

Dr. Gurdon Buck, President, in the Chair.

NEW VIEWS OF PHTHISIS PULMONALIS.

Dr. L. Weber read a resumé upon this subject, introducing it by reference to a monograph by Aug. Hedinger on "The Development of the Doctrine of Phthisis Pulmonalis and Tuberculosis" (Tübingen, 1864). Most of the ancient physicians held, with Galen, that pulmonary phthisis was caused only by a slow inflammatory process leading to ulceration; but a few, following Aretæus, added as a cause nodose indurations (φύματα), by whose softening and suppuration vomicæ were produced. The doctrine of Galen held firm, though not quite undisputed, sway down to the time of Laënnec, whose theory, by its simplicity, at once gained a strong hold upon the professional mind, which it has until very recently maintained. Laënnec identified phthisis and tuberculosis, and considered tubercle a peculiar neoplasm, anatomically demonstrable either as such or in its products, cheesy metamorphosis and vomicæ. From this point of view phthisis was pronounced wholly unmanageable, whether in the way of cure or of prophylaxis; yet Laënnec himself, with Rokitansky and Lebert, was afterwards forced by clinical observation to admit that spontaneous recovery was possible. Broussais, sustained by Andral and Reinhardt, while still acknowledging phthisis and tuberculosis identical, denied that tubercle was a pseudoplasm, and regarded it as the result of a slow inflammation; thus reverting to the position of Galen. An approach to a more satisfactory pathology is to be found in the masterly researches of Virchow, who distinctly separates the neoplasm known as *miliary tubercle* from all the other pathological products commonly grouped together with it as tuberculous. Already we begin to see the fruits of his labors in the admirable manner in which Felix Niemeyer and others have lately handled the subject, and in the results of an improved therapeusis based upon a sound pathology.

Under the *pathology*, Dr. Weber drew attention to the theory of Dr. William Budd (which we have given elsewhere), that tubercle is a true zymotic disease, specific in character, and, like other diseases of this class, is perpetuated only by the law of continuous succession; that the deposits of tubercular matter, which are of the nature of an eruption, either constitute or include the specific poison, and are the means of propagating the disease from person to person; and that there is reason to hope that, by means of proper disinfectants, we may ultimately be able to banish this scourge from the community. This theory is the less likely to find general favor now that the questions, what is tubercle? and what its relation to phthisis? are being so variously answered—experiments on animals tending to show that although tubercle may be reproduced by inoculation, yet there may be caused identical products by other inoculated matters. Opposed to Budd stands the school of Virchow and Niemeyer, which holds that the so-called tuberculous deposits in the lungs are by no means of uniform origin, but may arise from the cheesy metamorphosis of many substances; and that phthisis may originate as well from pneumonic or other deposits, local inflammation, etc., as from miliary tubercle. Of the views of Niemeyer, as given by the reviewer from the papers of Dr. Ott, in the *Berliner Wochenschrift* (Nos. 1–7, 1867), we append a brief summary, referring the reader for their fuller development to a condensed translation of Dr. Ott's work by Dr. W. T. Lusk, in the *New York Medical Journal*, December, 1867. The idea, held since Laënnec, that pulmonary phthisis is due to diathesis only, must be given up, experience having shown that all causes productive of bronchitis or hyperæmia and congestion of the lungs may also lead to it. It may exist in cases where not a tubercle is to be found anywhere in the body, and is then commonly traceable to some form of pneumonia—most frequently the chronic catarrhal. But direct irritation from foreign bodies, and especially from coagulated blood retained in the bronchi and alveoli after hæmoptysis, may have been the starting-point—this leading to pneumonia, with cheesy metamorphosis of the pneumonic foci, and this again to phthisis.

In his *diagnosis* Niemeyer distinguishes: 1. cases of phthisis dependent upon pneumonic processes; 2. those of phthisis with complicating tuberculosis; and 3. those of primary tuberculosis. In all these classes there is increased frequency of respiration, but in the purely tuberculous form this will be unaccompanied by dulness on percussion and bronchial breathing. The duration of the cough and catarrh, whether long preceding the fever and emaciation or from the first associated with them, is of great import, the former pointing to a pneumonic process, the latter to a tuberculous. The character of the sputa may indicate much; and a phthisical patient whose expectoration shows extensive destruction of lung-tissue, may be in less danger than another who, feverish, weak, and pale, coughs up only tough, transparent mucus. Fever is a constant symptom of both the pneumonic and the tuberculous forms, and the thermometer is as indispensable a guide in this as in other febrile affections. In the pneumonic forms the remissions are more marked than in those complicated with tubercle or primarily dependent upon it. Attention to the character of the fever, in conjunction with the physical signs, will enable us to determine whether the disease is pursuing the comparatively innocent course of chronic pneumonia and its sequelæ, whether a fresh inflammatory process is being set up, or whether the very grave complication of true tuberculosis has supervened. Chiefly to the fever are due the impoverishment of the blood and the loss of flesh, and the knowledge of this should greatly influence our treatment.

The *treatment* can be much more understandingly and hopefully pursued when we know that it is, in most cases, not with a true neoplasm, but with pneumonic processes, that we have to contend. Where genuine tubercle is present, the case is hopeless, and we can only aim at palliation. Persons with a tendency to either phthisis or scrofulosis demand the best hygienic conditions, and of these the most indispensable is plenty of fresh air. To secure this, residence in a warm climate during winter may be advisable. The diet must be abundant and nutritious, and rich either in fat or in fat-producing elements. Among these the malt extracts may well replace cod-liver oil where that is found nauseous. Sweet grapes have commonly a happy effect. The patient should be warmly clad in flannel. At the onset of an acute alveolar catarrh he should be

sent to bed, avoid superfluous coughing and talking, have his chest covered with poultices, and, if pleuritic pains persist, have leeches or cups applied. This simple treatment will save many a man from the establishment of a confirmed phthisical affection; and will often surprisingly arrest, in chronic cases, an exacerbation of the disease, shown by increase of the fever. Should these means fail, resort may be had to antiphlogistics, of which a favorite with the author is a pill of quiniæ sulph. (gr. 1), digitalis (gr. ss.), and ext. opii (gr. one-quarter), four times daily.

Other modes of treatment, which have lately been recommended from various sources, were next passed in review; and the paper closed with an account of the experiments of Lebert, Wyss, Villemin, and others, upon the inoculation of tubercle and other neoplastic and inflammatory matters from man to animals. The first positive results were reported by Villemin, who, in a communication to the Paris Academy of Medicine, December 4, 1865, and again November 15, 1866, gave his opinion that tubercle is inoculable and specific. But the greatest value attaches to the experiments of Lebert and Wyss, which are the most numerous (the details of forty-five are published), and bear the closest scrutiny. The summary of Lebert's conclusions is given in his own words: "Should we be asked, Have you produced genuine tubercle by inoculation? we should answer by a counter-question: What is genuine tubercle? what have we inoculated? where will you draw the line of demarcation between inflammatory product and tubercle, as it appears, aside from the lungs, in the peritoneum, pleura, adventitia of arteries, blood-vessels of the liver, connective tissue, etc.? With us, inflammation exercises a predominating influence over the whole doctrine of tuberculosis—a kind of inflammation which will develop itself the more rapidly, the poorer and less favorable we find the general nutrition of the body and its tissues, and the greater the absorption of pathological products and degenerated matter which has taken place in addition to it. The gray tubercle neither shows a specific cell nor even does it belong to a peculiar type of cells, and the same must be said of the pathological products of our experiments; by which, as well as by the nature of so-called true tubercle, it is shown that they stand very near to the inflammatory processes—nay, are most likely the products of inflammation."

The paper being before the meeting for discussion,

Dr. Noyes remarked, in connection with the pathology of tuberculosis, that until quite recently the tissues of the eye had been supposed free from liability to tubercular deposit; but lately, in several instances, miliary tubercle had been detected, during life, in the choroid—doubtless in the walls of its blood-vessels. Dr. Delafield had a specimen from the dead-house illustrating this. Dr. Noyes desired to hear the views of Professor Flint upon the subject of the paper.

Dr. Flint was not prepared for an elaborate discussion of the subject, but would touch upon a few points. While we should receive with great respect the opinions of a writer so justly distinguished as Niemeyer, yet conclusions so radical, tending completely to overturn the views long held by pathologists, should not be hastily adopted. Many of them, indeed, seem in conflict with clinical experience. Confining the term tubercle to the miliary form alone, and considering the deposits ordinarily called tuberculous as the products of chronic pneumonia, Niemeyer attributes this chronic pneumonia to an antecedent bronchitis, gradually extending to the alveoli. Now nothing is more common than to see a patient rather suddenly developing marked evidence of tubercle, where previous observation has failed to discover any sign of pulmonary inflammation. Again, nothing can be more certain than that bronchitis (as we apply the term, to bilateral inflammation of the bronchi) has no tendency to eventuate in tubercle; and moreover, a tuberculous patient contracting bronchitis experiences, as a rule, no aggravation of the tuberculosis. The doctrine that hyperæmia of the lungs is a frequent cause of tubercle, contradicts experience. In mitral lesions the mechanical conditions necessitate such hyperæmia, yet it may be considered well established that persons with these lesions are less subject than others to pulmonary tuberculosis.

Dr. Elsberg felt that the Society was indebted to Dr. Weber for presenting the views of Niemeyer; which well deserve our study, as being almost the only attempt to establish upon a scientific basis, of both clinical observation and post-mortem examinations, the doctrine which down to the time of Laënnec had been the prevailing one, and whose strong hold upon the popular mind was still to be seen. The recognized superiority of Laënnec's methods of diagnosis had greatly contributed to give an influence to his pathology of which we could hardly divest ourselves. But its inconsistencies must be acknowledged at least as great, and its failure to meet the facts of clinical experience as glaring, as could be charged upon the theory of Niemeyer; while its uniformly grave prognosis could not but affect unfavorably our therapeutic efforts.

Dr. Whitehead commented at some length upon various means of treatment. He thought that the use of iron and sulphur should be very guarded, as likely to increase the fever. The influence of climate was undeniable, but might be greatly modified by hygienic measures. Sea voyages were in general more harmful than beneficial. Muscular inertia must be regarded as favoring the development of the disease; hence exercise was an important prophylactic.

Dr. Herzog explained what he deemed a misapprehension of some of Niemeyer's views; and wished to call attention to the illustration they had received from the labors of Professor Buhl, one of the ablest observers in Europe. Buhl's conclusions are, that although miliary tubercle is to be distinguished from the direct results of pulmonary congestion and of bronchitic and pneumonic processes, yet these often bear a causative relation to it. The inflammatory exudation, by its mechanical pressure, so interferes with the nutrition of the tissues as to give rise to those forms of degeneration which may result directly in phthisis and secondarily in the production of true tubercle. With the pulmonary infiltration is almost uniformly associated a similar condition of the mesenteric glands, which again seems to have its influence upon the development of tuberculosis. Dr. Herzog spoke of the impossibility of diagnosing simple miliary tubercle by the physical signs, and of the importance, in this regard, of attention to the form of the accompanying fever, as pointed out by Niemeyer.

An animated discussion ensued among Drs. Flint, Lusk, Elsberg, Herzog, Weber, and Post, in the course of which Dr. Flint remarked that while Niemeyer regards tubercle as resulting, in a considerable number of cases, from the irritation of coägula left after hæmoptysis, experience has conclusively established that those cases of phthisis attended by hæmoptysis are the ones which generally pursue the most favorable course.—Dr. Post strongly endorsed this view, and related the case of a patient who had been subject to frequent and profuse hæmorrhages for thirty years.—Dr. Lusk understood Niemeyer that hæmoptysis might cause phthisis, which was amenable to treatment, but not true tubercle.—Dr. Herzog and Dr. Weber explained that it was active hæmorrhage, from excitement, exertion, etc., which, oc-

curring in a lung previously considered sound, might, by the direct irritation of the coagula as foreign bodies, give rise to abscess or chronic pneumonia; and these to phthisis. Dr. Herzog could understand how hæmorrhage occurring in the course of the disease, from the breaking down of the infiltrated tissues, might, by relieving the vessels from pressure, so affect the circulation as to cause improvement in the patient's condition. But he thought it might lead to results either immediately fatal, or remotely so from the formation of abscesses, etc.

Dr. Elsberg desired Dr. Flint's views upon the doctrine of the specific nature of tubercle, as propounded by Laënnec, and still generally accepted.

Dr. Flint replied that some of Laënnec's ideas were exploded, as that "crude" tubercle (miliary granulations) always precedes and constitutes the "seeds" of tubercle as commonly understood. But on the point in question he must incline to the affirmative side. We have here a disease of a specific character, and doubtless dependent upon a specific diathesis; differing widely from acute pneumonia in its manifestations, aud in many respects also from chronic pneumonia. Acute pneumonia commonly attacks the lower lobes of the lungs, tubercle the apices; pneumonia, both acute and chronic, is commonly unilateral, tubercle bilateral. The formation of abscesses in tuberculosis is exceedingly rare.

Stated Reunion, Friday, December 13, 1867.

Dr. A. C. Post in the Chair.

A NEW INSTRUMENT FOR ARTERIAL COMPRESSION.

Dr. Van Gieson read a paper entitled, "A New Method of Arterial Compression by Means of a Sectional Ligature." After a resumé of the more recent modes employed for the complete or partial occlusion of arteries, he described an invention of his own, designed to effect either of these objects, and applicable more particularly to arteries in their continuity, as in the treatment of aneurism. The apparatus, as exhibited, consists of two small silver tubes, each having a shoulder near one end, and a slight curve at the other. The size of the curve should correspond with that of the artery to be operated upon, so that when the two curved extremities are passed down upon opposite sides of the vessel, they may together embrace it below. A piece of wire and a wedge of cork complete the instrument. To apply it, the artery having been exposed and the wire passed beneath it by an aneurism needle, a tube is slipped over either end of the wire, until the two curved ends meet beneath the artery; the opposite ends, remaining outside the wound, are then approximated until the desired degree of compression is attained, when they are fixed in position by placing the wedge between them, and winding the free extremities of the wire around the shoulders. The apparatus is made immovable by adhesive strips, or by a strap fastened about the limb, and provided with a clamp for the purpose. In place of the cork wedge, the doctor proposed to graduate the pressure by means of a spiral spring and a screw. The wire does not touch the artery after the tubes are applied, and in removal it may be drawn out while the tubes are held in situ, to avoid the chance of laceration. The inventor claimed for his instrument facility of application and removal, and ease of graduating the compression. He gave the details of two experiments with it, and desired to see it further tested.

Dr. Wm. B. Lewis next read a carefully condensed resumé of what has lately appeared in medical literature upon "The Pathology of the Urinary Organs, and of their Secretion." Some discussion followed upon the propriety of incising or puncturing the integument, for the relief of anasarca in Bright's disease. Dr. Van Gieson related a case of incision, resulting in severe erysipelas. Dr. Sayre was always accustomed to make numerous small punctures with a tenotome, which rapidly drained away the fluid, and rarely, if ever, gave rise to erysipelas.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Nov. 27, 1867.

Dr. B. H. Sands, President, in the Chair.

VALUABLE EXPERIMENTS ON LIGATION OF ARTERIES.

Dr. Benj. Howard presented a series of specimens, stating, that as he had six recent cases to exhibit, he would in description confine himself to the chief points in the respective cases, and would endeavor to avoid a repetition of anything expressed upon the same subject upon a previous occasion.

The history of the first specimen I present, marked No. 5, is as follows:—Desirous of observing the result of a simple apposition of the internal coats of an artery, I prepared a band of lead, about a line in width, smoothed all sharp edges, and polished it brightly; its length was such that when doubled upon itself, it sufficiently exceeded the diameter of the artery as to allow of its being passed around the vessel, and the two ends clamped together, without any mechanical injury to the coats of the vessel. I applied this ligature in the manner described, to the right common carotid artery of a sheep, on the 17th of October. On the 23d of November, being thirty-seven days after the operation, I made an incision in the line of the cicatrix, which was well healed, when I found close beneath the surface, the ligature in a state of dryness, and waiting to drop from the cicatrix. The deposit of fibrine is seen to have been quite extensive, forming a solid mass from the artery to the integument. Through the whole extent of this will be observed a sinus communicating with the place where the ligature was found, and the point of its application.

The longitudinal section of the artery shows that the occlusion of the artery by fibrine at the point of ligation, and by a well-formed plug above and below it, is perfect. The ligature appears to contain in its embrace, the part of the artery it was made to include.

No. 6.—October 17. I applied to the right common carotid of another sheep a lead-wire ligature, tying it loosely, diminishing calibre about two-thirds. November 22d, being thirty-six days after, I found this cicatrix healed, but at about its middle a small fluctuating tumor. On making an incision through it along the line of cicatrix, the tumor was found to contain about a drachm of very thick pus, in which I found the ligature. The deposit of fibrine will be seen to be greater in this than in the last specimen; and through its whole extent, from its point of application to the abscess, the ligature had ulcerated its way. It is very interesting to observe the plug of fibrine which is clearly shown in situ, by which the whole rear track of the ligature has been closed up as it advanced toward the integument.

The longitudinal section shows, as do others, that at the point of ligation, for the portion of artery destroyed by the ligature, is substituted a solid mass of fibrine, and that the artery is thus perfectly occluded, as well as by a clot above and below.

No. 10.—October 31. To the right carotid of a sheep I applied a flat silk ligature outside its sheath, diminishing the calibre of the artery barely one-half. November 23d, being twenty-three days after, I found the cicatrix soundly healed, the fibrous deposit smaller than

in either of the two preceding cases; and you will observe that the longitudinal section of the artery reveals the same dense fibrine substituted for the canal of the artery at the point of ligation.

There is no sinus or trace of the ligature visible in this specimen, as there was in the other cases. But we know it did escape, because it was found outside the wound, the free end having been fastened there at the time of ligation.

No. 7.—My object in the case now before us, was to observe the effect upon an artery of a simple cessation of function. Accordingly, October 31st, I applied three silver-wire ligatures, the second being about twelve lines above the first, and the third about four lines above the second.

The first was tied with little less than the average tightness commonly used in the silk ligature; the second broke close to the loop, so that I had but to cut off the free end; the third I tied with firmness, but with more caution, to avoid repetition of the accident incident to the second; twenty-two days after I vivisected this specimen, the cicatrix was not firm, and the hæmorrhage was great. It will be seen that the calibre of the arterial canal, between the ligatures, is very much diminished, and is occupied toward its centre by what appears to be an organized clot, which, as we approach the points of ligation on either hand, becomes a firm plug of fibrine.

The history of the disused artery is, however, of but small importance, compared with that of the ligatures as here observed.

The first ligature cannot be found. The second is also wanting; and from the original site of each throughout the fibrinous mass, toward the cicatrix, you will observe an open sinus through which they have been discharged. The third ligature, applied with less force, will be seen lying loosely within the artery at the internal end of the upper sinus, apparently waiting to be extruded. The occlusion about each ligated point is complete.

No. 9.—This is the right carotid of a sheep which I ligated October 31. The ligature was of silver wire, the same as that used in the last specimen exhibited. I tied it by a single flat knot, and cut off the ends closely. I applied it outside the sheath, tying loosely, and diminishing the calibre of the artery about half or two-thirds.

November 23d, being twenty-three days after the operation, I found the cicatrix quite sound. The vivisection was accompanied with very little hæmorrhage, and here is the specimen. There is but little deposition of fibrine, and a longitudinal section of the artery reveals the ligature in situ, as applied; the looseness of its application being manifest by the size of the piece of whalebone passed through its loop. It will be seen there is no sign of suppuration or sloughing, but only the deposition of fibrine for the envelopment of the ligature, and that due to inflammation following the laceration of the areolar tissue in the performance of the operation.

Here is a specimen exhibiting the difference between the effect of the "surgeon's" or flat knot and the ordinary knot, upon the internal and middle coats.

In neither case are the divided edges of the inner coats in apposition; in the former case you will observe, by means of the lens which I will pass around with it, that the divided ends are curled upward, their flat surfaces forming a plane representing the diameter of the artery, at right angles with its long axis; they are therefore not in apposition with each other, but only in juxtaposition.

The ordinary round knot, you will see, has produced a puckering and partial laceration of the inner coats, the plications terminating like radii in the centre of the transverse section exhibited.

The specimens presented exhibit in each case where a loose ligature has been used, whether of silver, lead, or silk, perfect occlusion of the arterial canal.

When the loose ligature has consisted of lead or of silk, ulceration and suppuration have occurred, with extrusion of the ligature toward the surface.

Equally with other specimens previously presented, these exhibit that *every* TIGHT *ligature of either kind, and every* LOOSE *ligature except the* SILVER, *has been extruded; but the "loose silver ligature" is followed by obliteration, fibrinous and extensive, with exemption from sloughing, from suppuration, and from extrusion of ligature common to every case of other kinds exhibited.*

Here are the facts, as far as they go. The theory which after a sufficient accumulation may be woven out of them, may be worthy the consideration of the Society. As to the causes of the differences in the results, I may be allowed to suggest that the questions in order might be:

1st. *The ligature.*—What relation exists between the different qualities of the different ligatures, and the difference in the results exhibited respectively?

2d. *Looseness.*—In the absence of sudden lesion of the artery, and of sudden complete strangulation of the vasa vasorum, are not the parts better able to perform the new task suggested and assigned to them?

Is not the operation, the shock, the local and general disturbance more moderate, than in the case of a tight ligature?

Is not the gradual accommodation of the collateral branches to the demand instituted on the application of a loose ligature, sufficient to account for the absence of the great oozing common only to all the vivisections made in the region of a recent *tight* ligation?

POST-MORTEM DIGESTION OF THE STOMACH, ETC.

DR. LEWIS SMITH presented specimens of stomach, and remarked upon them as follows: At a recent meeting of this Society, I presented a lung which seemed to be gangrenous. The patient from whom it was taken was a foundling, who died at about the age of one month. It will be recollected that the posterior part of each lung in this specimen presented a dark gray color, and was very much softened. The finger readily penetrated it, and in places the lung was so decomposed as to be almost diffluent. Other portions of the lungs and the other viscera had undergone no perceptible alteration. I was not present at the post-mortem examination in this case, but Dr. Gouinlock, of the house staff of Charity Hospital, who made the post-mortem examination, states that it was made about twelve hours after death.

I present, this evening, two other specimens, one which I have preserved since the commencement of the year, the other obtained at a recent post-mortem examination. The infants from whom these lungs were taken, were also foundlings, dying when a few months old, in a state of exhaustion.

I have, from time to time, met with such specimens, probably as many as ten, in the course of six or eight years. I had been led to regard these lungs as probably gangrenous, chiefly by exclusion; for I could not see what else the state could be. At the close of the meeting referred to, however, a gentleman not a member of the Society, a foreigner, suggested that what resembled so closely gangrene in its gross appearance, might be the result of post-mortem digestion. I was sure that there had been no escape of the gastric juice directly into the pleural cavity, but the explanation offered was that it passed up the œsophagus and down

the trachea and bronchial tubes to the lungs, by the movements to which the body was subjected in carrying it to the dead-house.

The reasons for believing these lungs gangrenous are mainly those afforded by the appearance. Rilliet and Barthez, who have written exhaustively on this disease, state that in nearly all cases which they have met, the patients were exhausted by previous disease. The gangrene was secondary. As regards the etiology, therefore, these cases would correspond with those observed by Rilliet and Barthez, for these foundlings were in a reduced state.

On the other hand, as reasons for considering these lungs not gangrenous, may be stated the fact, that they did not have the fetid odor, nor was the breath of these children fetid. The authors, however, from whom I have quoted, state that fetor of breath is not usually present in cases of gangrene of the lung in children. They observed it in only five cases in sixteen, and in only three was it marked (*très fétide*). It would seem, also, that the lungs which I have presented could not be gangrenous, since it is improbable that I could meet as many as ten specimens of gangrene in six or eight years, and all under the age of one year, when Rilliet and Barthez only observed sixteen, all over the age of two and a half years. Again, the affected portions were not surrounded by solidified or inflamed tissue, as they ordinarily are in gangrene.

In order to determine what the effect of the gastric juice would be on the lungs, I removed the stomach and its contents from an infant about twelve hours after death, and placed it in one of the pleural cavities. It was opened so as to allow a more ready escape of the gastric juice. The stomach, with its contents, was also added from another child, and incisions were made in the lung, so as to facilitate the action of the gastric juice. After twenty-four hours the lung was examined, and the result was negative. There was only a slight yellowish staining of the lung. Dr. Gouinlock, of the house staff of Charity Hospital, repeated the experiment, with also a negative result.

While these experiments were being made, we examined the body of an infant who died of entero-colitis, at the age of about six months. The evidences of inflammation of the colon were very decided. The coats of the stomach were softened throughout their whole extent, so as to be easily torn, but were not perforated, although the mucous membrane seemed to be almost wholly dissolved, so as to present a gelatinous appearance. The stomach had a brown color, and was perhaps half filled with contents of the usual appearance. The surface of the left lobe of the liver adjacent to the stomach presented the same brown color, which was superficial, as did also the part of the diaphragm which lies over the stomach, and also the surface of the left lung contiguous to the diaphragm. This part of the diaphragm was also softened. On opening the œsophagus, it was found of a brownish or leaden color, from the cardiac orifice to the distance up the tube of about two and a half inches. There were several small ulcers, apparently involving only the mucous membrane in this part of the œsophagus, while the upper portion of this tube was healthy. On one side, all the coats of the œsophagus presented the same appearance, and seemed somewhat softened, but without perforation, and the surface of the lung, which lay against the œsophagus, was also browned, and apparently eroded to the depth of one or two lines. There had evidently been a transudation of liquid through the coats of the œsophagus, as well as those of the stomach.

The color of the lung produced by the transudation was somewhat like that of the specimens which I have presented, but not so dark. These observations evidently do not indicate positively the nature of the change presented by the lungs which I have presented. The negative result of the experiments proves nothing, because we know that post-mortem digestion does sometimes destroy tissues. I have myself seen the œsophagus severed from the stomach, by this digestion, in the child, and some time ago a specimen was presented to the London Pathological Society, in which the gastric juice had perforated the œsophagus, and had made a hole in the left lung. There are, so far as I can see, but three modes of explanation of the appearances which these lungs present, namely, by supposing that the affected portions are gangrenous, or that they have undergone post-mortem digestion or ordinary post-mortem decomposition. The arguments against either explanation are strong. Those in reference to the first two I have sufficiently alluded to. The arguments against the last explanation, that of post-mortem decomposition, are the short time after death (in one case about twelve hours) at which the autopsies were made, absence of putrid odor, absence of any evidences of decomposition in other portions of the lungs and in the other tissues. For these reasons I think that the Society will agree that these specimens are somewhat remarkable, and that we do not yet know certainly their character.

Correspondence.

MUSIC IN CHOREA.

To the Editor of the Medical Record.

Sir—In your issue of December 2d, I noticed an extract taken from the *British Medical Journal* on the "Effects of Music on the Insane."

It reminds me of a case of Chorea which came under my care several years ago. It was a very interesting case, notes of which were taken with a view to their publication at some convenient time; but they have been mislaid, and I must depend solely on memory for the description. As it appears to me, it corroborates in a measure the theories expressed in the extract alluded to; and opposes, as far as a single case can, the views of many modern pathologists, that Chorea is intimately associated with, or allied to rheumatism, hence, primarily, a blood disease.

The case occurred in 1862. The subject, a young lady about seventeen years of age, of ordinary parentage, intelligent, with a florid complexion, of medium stature, form plump and rounded, previously healthy, with the exception that about two years previous she had Chorea of ordinary severity, which was treated successfully with Fowler's Solution. A short time anterior to the present attack, I prescribed Fowler's Solution for a slight eczema, and this she was taking when she began to notice slight involuntary movements of one arm. This fact was taken as fair evidence that, as this remedy appeared to excercise no power as a preventive, it promised little or nothing as a specific, which by many it is believed to be; therefore, as the case continued to grow worse, the arsenic was discontinued, and she was advised to use sulphate of zinc, as ordinarily prescribed for Chorea. No amelioration followed; on the contrary, the convulsive movements steadily increased. Cohosh, or black snake-root, as recommended by Prof. Wood in his Practice of Medicine, was ordered, the zinc remedy to be continued; still the symptoms steadily and rapidly increased in severity, and the convulsive action became so general that apparently every voluntary muscle of the whole body was involved.

Such a case I never saw, so violently was she thrown about from one part of the bed to another. To sit or stand was utterly impossible. Even her bed was faithfully guarded to prevent her being precipitated to the floor. One remedy after another was resorted to until tonics, antispasmodics, anodynes, stimulants, etc., were exhausted. Still the scene was unchanged, only that the picture was more and more horrible. No remissions for sleep; no repose whatever. Scarcely was there a moment's respite to receive food. Tongue sore from being frequently caught between the teeth, flesh wasting, limbs discolored and swollen by repeated bruises, exhaustion advancing rapidly. Days passed away—as many as ten or twelve—and all the while she was completely conscious of her anguish.

An officious neighbor, as the case began to assume a threatening aspect, suggested a trial of *music*. The suggestion was, however, dismissed with scarcely a favorable thought. After a few days, the remedy was again proposed, and by this time I had learned that the notion was quite prevalent in the neighborhood that music was a valuable agent in the treatment of St. Vitus' dance. I remarked that it was undoubtedly worthless, and especially so in a case of such severity, and supposed it was again dismissed. At my next visit on the morning following, to my utter astonishment, I found a violinist and his instrument "on hand," and my patient decidedly more quiet! He was invited, it appeared, the evening previous, and taking an adjoining room, he played at intervals some piece of plaintive music, the effect of which, as it was described by the attendants, was truly marvellous. She slept a little before morning, and to abbreviate the recital, the cure was rapid and complete.

In conclusion, allow me to remark that I have searched my limited library, and find no allusion to music as a remedy in Chorea:—that is, a remedy, *per se*. Récamier, at the Hôpital des Enfans Malades, at Paris, has long practised systematic movements of the affected muscles, *sometimes accompanied* with music.

Crescent, N. Y., Dec., 1867. SAM'L PETERS, M.D.

TO WHOM DOES THE PRESCRIPTION OF A PHYSICIAN BELONG?

TO THE EDITOR OF THE MEDICAL RECORD.

THERE seems to me to be a risk of so great a fallacy in your position in regard to this inquiry, that with the greatest desire to attend to my own business, and above all to avoid controversy, I must beg of you to go over the ground afresh, and seek for more information on the subject before considering it definitely settled. It is an important subject, and one which threatens to widen the breach between medicine and pharmacy; and that interest will be most damaged which obtains judgment in its favor on insufficient grounds. In a discussion now of some years' standing, legal opinions have been pretty freely quoted on both sides, with the effect upon some of us, at least, of leading to the inference that such opinions must differ as much in value as in the position taken. Therefore, lest some of us should fall into a grave error which may do much harm in a direction where mistakes are not easily corrected, let me beg of you to suspend judgment until the subject is more thoroughly examined on all sides.

By the action of a neighboring medical society, the subject is now before the American Pharmaceutical Association, a body which, from its interest in the matter, is entitled to a hearing, and the undersigned proposes presenting his views on the subject to the New York State Medical Society, at its approaching annual session. Very respectfully yours, E. R. SQUIBB.

Medical Items and News.

NEW YORK PATHOLOGICAL SOCIETY.—The following officers have been elected for the ensuing year: President, Dr. W. B. Bibbins; Vice-Presidents, Drs. T. M. Markoe and L. A. Sayre; Secretary, Dr. Geo. F. Shrady; Treasurer, Dr. W. B. Bibbins.—*Committee on Admissions*, Drs. Weir, Whitehead, Rogers, Krakowizer, and Shrady. *Committee of Publication*, Drs. Shrady, Eliot and Rogers.

CÆSAREAN SECTION.—We have received from Dr. Dibble of New Haven a report of a successful case of Cæsarean Section performed by Dr. Townsend of that city. We shall publish the details at an early date.

THE MISSOURI MEDICAL ASSOCIATION was duly resuscitated on the 12th of December, after a long sleep of ten years, and has inaugurated some wise measures relating to the future prosperity of medicine in the State. A communication from the St. Louis Medical Society, asking of the Legislature a Board of Medical Examiners to be appointed by the Missouri Association, with power to grant licenses, was adopted, and a committee appointed to prepare a suitable memorial. They also endorsed most emphatically the stand taken in the matter of medical education by the recent Convention of Medical Teachers.

BANQUET OF THE INTERNATIONAL MEDICAL CONGRESS.—The day of the banquet had been intentionally set for about the middle of the sitting of Congress, in order that it might serve as an interlude, and at the same time bring together a large number of convivials. So of the two hundred subscribers not one failed to be present.

The magnificent hall of the Grand-Hotel did not appear too large for the four or five long tables stretched out side by side. As seats were not taken until half-past eight, there was ample time in the waiting-saloon for each one to get acquainted; this was very desirable, inasmuch as the hall of the Congress was not favorable for meetings, or for presentations or hand-shaking. M. Frerichs, fluttering with ribbons and decorations, and elegant in manners; and M. Virchow, in a solid suit of black, very dry, with a false collar cutting his ears, were the objects of special curiosity. The dinner was animated, brilliant, lively; men jovial in certain quarters (on M. Ricord's side, it was said). The celebrated syphilographer was seated to the left of the president, and M. Virchow to the right. With the dessert came the toasts. M. Bouillaud, the president, opened; then followed others. Among them M. Ricord drank to the extinction of venereal diseases, and the suppression of that specialty.—*Gazette Hebdom., Aug.* 30, 1867.

A BRIEF DESCRIPTION OF STELLINE, STELLURINE, CONCHOIDINE, AND PIGMENTINE,

WITH SOME OF THE PATHOLOGICAL STATES AND CONDITIONS CAUSED BY THEIR FORMATION AND PRESENCE IN THE HUMAN BODY.

By J. H. SALISBURY, M.D.

STELLINE.

Stelline is a pathological product, formed by the parent cells in the human body, only in disease. It may be formed at any given time, by one class of parent cells only, or by all.

When one class of cells becomes so disturbed in their functions as to form this body, this condition, if not removed, has a tendency to extend to the other classes of parent cells, and soon the entire organism is under its influence.

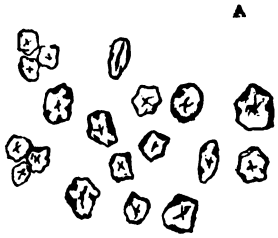
When this body is formed in the system, its presence produces a greater or less amount of irritation or disturbance, according to the state of the system, the drinks and food taken, and the hardships and other baneful influences to which it is exposed. Its presence may be confined for a while to either the blood apparatus, the skin, or to the mucous membranes.

The tendency is for it to pervade the entire organism, when once the conditions are present for its formation. Its principal formation, however, may be for a long time confined mainly to one class of parent cells.

For instance, when this constitutional diathesis is present, and there is a weakened and irritable c ndition of the bronchial membranes from any cause, this body is likely to be formed here first, and continue to be formed largely in this locality for a long time, producing, perhaps, asthma and bronchial catarrhs in their various phases, without its being formed to any great extent by parent cells in other parts of the organism.

It may be formed for some time by the parent cells of the blood apparatus, and appear but in small quantity elsewhere. It may be formed largely by either the mucous membranes or skin, and be but slightly present in other parts of the body. The tendency, however, is for it, when once established, to pervade the entire organism, and to be discoverable by the microscope in the blood, and all the secretions and excretions, and in and on all free surfaces of the body. Whether found locally or generally distributed, the treatment is mainly the same, which should in all cases be directed to the removal of the cause.

This body in shape is sometimes oval and flattened, but almost always either polyhedral or polygonal, with a peculiar radiating or stellated fracture in the centre. From the peculiar characteristic fracture I have given this body the name *stelline* (*a*). Its composition is not yet determined. Its presence produces much disturbance. If formed to any great extent in the blood apparatus, its presence has a tendency to produce languor, fatigue, restlessness, irritability, despondency, wakefulness, constipation, palpitation of the heart on any excitement, with more or less irregularity of beat; dull aches and pains in the cardiac region and chest, back of neck, small of the back and head, with more or less dizziness. In reading, the lines and words sometimes run together. In sewing, the head becomes bewildered. Objects seem to tremble as if heated air were rising before the eyes; and the patient reels at times in walking. The muscles, under the influence of exertion, ache, and become soon exhausted. The limbs prickle, and manifest premonitory symptoms of paralysis. The head becomes at times numb, constricted, and bewildered, and thinking is painful and difficult. The memory is impaired, and the mind readily gives way to anxiety and trouble, and frequently indulges in melancholy forebodings. Small crosses become painfully oppressive, and the patient frequently contemplates suicide; but is fearful to execute his thoughts, though he sometimes does.



A

In this condition some part of the body may become temporarily paralyzed; and in persons of a peculiar sensitive nervous system, either cataleptic or epileptic paroxysms may result. If stelline is being formed in the skin to any great extent, it (the skin) becomes often dry and furfuraceous, though sometimes, especially if there is derangement of the pulmonary apparatus, or a rheumatic tendency, the skin may be covered with a cold, clammy, sticky sweat, which has a sour smell. Under such conditions the cuticle will be found full of algoid spores and filaments, and sometimes filled with a peculiar fungoid spore, which has a brilliant nucleus.*

If this body is formed largely by the mucous membrane of the bronchi, the patient will be troubled with severe bronchial coughs, and, perhaps, asthmatic attacks; or, perhaps, under certain conditions, be afflicted with "*rose*" or "*hay asthma.*" This is purely bronchial gravel. Such cases cannot be cured without removing the cause.

If formed largely by the nasal mucous membranes, nasal catarrh of an obstinate character results, which will not yield till the cause is removed. If this body is being formed largely by the mucous membrane lining the uterus, there results severe uterine catarrh, which will not yield permanently till the cause is removed.

If this body is being formed in the tubuli seminiferi spermatorrhœa is the certain result. As the little plugs of stelline come away, they produce irritation, and excite dreams and emissions. It is useless to undertake to cure such cases without removing the cause. If this body is being formed largely by the mucous membranes lining the urinary organs, more or less irritability of these organs will result.

The formation and accumulation of stelline in the blood apparatus, simply, with the abnormal states and conditions arising therefrom, constitute a disease which may be designated by the name *stellinemia*. That arising from the formation and accumulation of this body throughout the system, may, for like reasons, be called *stellystema*.

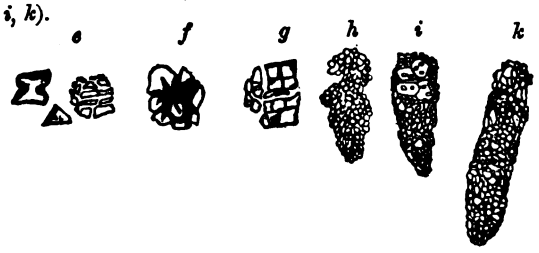
STELLURINE.

This is a pathological product, formed in disease by the parent cells. It may occur in the blood; in the epidermic layer of the skin; in the urine and fæces; in the discharge in uterine catarrh; in the expectoration; and in the secretion of bronchial and nasal catarrhs. Wherever it occurs it produces irritation and disturbance. It may be absent or occur in small or large quantity in the blood; and be absent or occur in small or large quantity in any or all of the other localities above named. Where it begins to be formed by

* Mikros, iris (Salisbury).

any one class of parent cells, the tendency is for the same pathological condition to extend to the others; and in a longer or shorter period—according to the exposures and condition of the system—it becomes a general or constitutional trouble. I supposed for a long time that this body was cystine.

The crystals are usually irregular in shape, very transparent, tender and friable, and highly refractive. They have a remarkable tendency to fracture into many fragments, as the blood cools and contracts by clotting, while being viewed between the slides of the microscope. The crystals, on the least pressure, frequently fly asunder with considerable force, scattering the pieces in every direction—like glass badly annealed. The fracture is more or less conchoidal, and frequently starts from the centre of the crystal and radiates in various directions, dividing it into two, three, four, or more parts, and sometimes into as many as fifty or one hundred — minute, sharp, angular fragments (*e*, *f*, *g*, *h*, *i*, *k*).



From the stellated character of the fracture I have given to this body the name *stellurine*. It is distinguished from stelline by the peculiar shape of the crystals. Stelline has like it a tendency to fracture, but to a much less degree.

Cystine differs from this body in not being inclined to fracture, and in being less transparent, refractive, and friable.

E, *f*, *g*, *h*, *i* represent crystals of stellurine as seen in the freshly drawn blood before and after fracturing.

This body, when present in the blood to any great extent, like stelline, produces dizziness, impairment of memory, despondency, wandering rheumatic neuralgic pains and aches, nerve irritability, sleeplessness, and often a strange, mixed-up, "crazy feeling" (as patients describe it) in the head. The head feels frequently as if a band were drawn tightly around it; objects viewed, tremble as if heated air were rising before them; and occasionally the patient reels in walking as if intoxicated.

The heart palpitates on excitement, and the beat becomes sometimes intermittent, and a dull uneasy ache, with occasional sharp transient pains, occurs in the cardiac region. There is a tendency for the muscles of organic life to lose partially their tonicity, the heart-beat becoming more or less deranged, and the peristaltic action of the bowels impaired. There is frequently a strange mixed-up numb feeling about the head, with prickling numb sensations in the extremities.

The voluntary muscles readily tire and ache when over-fatigued. Such persons, under the proper conditions, may be affected with nasal, bronchial, or uterine catarrhs, with asthma, "hay" or "rose fever," with one form of rheumatism, with cataleptic or epileptic manifestations, with urinary or seminal disturbances, with strange hallucinations, and even insanity, and sometimes with more or less extended paralysis.

Medical writers have been in the habit of viewing many local manifestations of disease as purely local difficulties. For instance, oxaluria, cystinic uria, phosphuria, etc., which are treated as local troubles, are, as a general rule, really constitutional pathological states—these several bodies being formed in the blood, expectoration, fæces, etc., as well as in the urine. The presence, as a general rule, of any abnormal product, in any given part of the organism, is but a local manifestation of a constitutional pathological formation, which will be found to show itself sooner or later to a greater or less extent in other localities.

Wherever we have oxaluria, cystinic uria, phosphuria, stellin-uria, stellurin-uria, etc., we have also oxalemia, cystinemia, phosphemia, stellinemia, stellurinemia, etc. This whole matter will be more fully treated of in a paper on this subject now nearly ready.

The formation and accumulation of stellurine in the blood apparatus simply, with the pathological states and conditions arising therefrom, constitute a disease which may be designated by the name *stellurinemia*. That arising from the formation and accumulation of this body throughout the organism, may, for similar reasons, be named *stellurystema*.

The formation and accumulation of either stelline or stellurine, or both, or of cystine, oxalate of lime, or the phosphates, in the blood apparatus, may, under the proper conditions, result eventually in organic disease of the heart. These bodies all have a tendency to partially paralyze the muscles of organic life. The muscular power of the heart at first becomes weakened, or its muscular tonicity so impaired, that any considerable exertion or excitement, physical or mental, excites the heart to increased activity, while during passive conditions the beat is usually slow and irregular. In this state, the circulation is either too sluggish or over active. The heart responds to every little excitement and exertion to which either body or mind is exposed. Dull aches and pains are frequently felt in the cardiac region. The heart sounds are all normal, for a long time after the disease has begun to insidiously work its sure way. To the unaided senses, there appears to be no organic disturbance; hence the pathological condition of the organ is supposed to be sympathetic or functional. Organic changes are, however, slowly in progress. The lining tissue of the heart and large vessels leading to it, becomes thinly or thickly studded with minute microscopic granulations or eminences. These, as they grow, take on a smaller pedicle and a larger body. They are really minute thrombi, made up of fibrin, inclosing minute crystals and granules of the bodies before named. These bodies are the specific cause of the thrombi. The thrombi frequently become detached and float, as emboli, freely in the blood stream, unless so large as to be checked in their course by the capillaries.

The formation of minute thrombi goes on step by step, till by and by the heart sounds become abnormal, when no one doubts the presence of organic disease. It may however now, perhaps, be too late to repair the damage done, or even to check the progress of the pathological conditions and formations already far advanced toward a fatal issue; while if the disease had been discovered and treated earlier, there would have been but little difficulty in its removal.

Here then again the microscope comes in, and reveals to us with certainty the cause of a most dreaded and fatal disease, while yet it is in a stage that is amenable to treatment.

PIGMENTINE.

This is a peculiar brownish-yellow coloring matter, that occurs in the blood in all cases where pigmentary matter is being deposited in an unusual degree—either in spots or generally over the surface—in the under layer of epidermic cells. It occurs in thin plates, or laminæ, irregularly fractured in various directions, as represented at *l*. Patients hav-

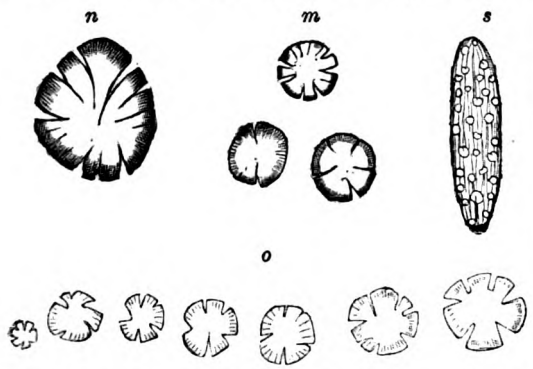
ing this substance forming largely have a peculiar brownish-yellow, bronzed, sickly hue. It is found in larger or smaller quantity, according to the extent and depth of the pathological coloring. In such cases, the digestive apparatus has become more or less deranged — usually from defective alimentation and exposures; and the blood is found generally thin, and its histological elements more or less broken down—the blood glands performing their office of forming blood imperfectly. Iron, quinine, iodide potassium, and good healthy alimentation are valuable means for removing this disease.

To the formation and accumulation of this body in the blood apparatus and the resulting local and systemic disturbances I have given the name *pigmentemia.*

CONCHOIDINE.

Conchoidine is a peculiar body, found only occasionally in the blood. It is usually—in shape—of an oval or circular disc-like form; more or less flattened in the direction of the shortest diameter. It occurs almost always with fractures extending from the circumference toward the centre.

m, *n*, *o*, and *s* represent this body as it appears in the blood. It resembles very much a fat globule, so far



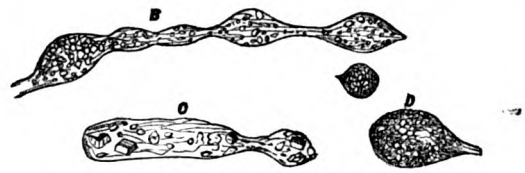
as its lustre and refracting characters are concerned; but, unlike it, it fractures into fragments which preserve their form. These broken pieces are sometimes met with in the blood.

Of the causes which produce these bodies, or of their chemical constitution, or of the pathological conditions excited by their presence, but little has as yet been determined. They occur in the blood — usually — in connection with other abnormal insoluble products. They undoubtedly give rise to more or less systemic disturbance. To the group of abnormal states and conditions excited by the presence and accumulation of this body in the blood apparatus I have, for present convenience, given the name *conchoidemia.*

REPORT OF THREE CASES.

Case I.—*b*, *c*, and *d* represent emboli, from the blood of a lady, Mrs. G. D., of Cleveland, Ohio, who has been laboring under *stellinemia* and *stellurinemia* for several years. About eighteen months ago, she gave birth to a child, which soon died. She seemed to get along quite well after the labor; but as soon as she was able to get up and move about, she found the least exertion fatigued and prostrated her. As soon as she assumed the erect position, a peculiar mixed-up, dizzy, numb feeling would come over her, and she would have to lie down. Her appetite was good, and she kept in good flesh.

About six months after the labor, she came into my hands. On examining her case I found she was laboring under the diseases previously named. Her blood contained many granules and crystals of *stelline* and *stellurine* (*a*, *e*, *f*, *g*, *h*, *i*, *k*), and also many emboli, —*b*, *c*, *d*—filled with crystals and granules of *stelline*



and *stellurine*. The urine also contained these bodies in large quantity.

She had been under treatment for ulceration of womb, and softening of brain.

On examination, found her womb trouble simply catarrhal and slight, and there were no evidences of brain softening.

She seemed to have no muscular power or endurance. The least exertion would bring on an exhausted, half-paralyzed condition of the whole body, with a peculiar mixed-up, dizzy feeling.

The heart sounds were normal, but the pulsations were at times quite weak and irregular. Listening to reading or talking for a short time would frequently tire her, the same as physical exertion, and would bring on sometimes the same bewildering sensations.

Bowels very constipated — almost paralyzed — and urine high-colored, scanty, and of a sp. grav. of 1.030 and upward.

The least exertion would excite the flow of perspiration; although she had most of the time, when still, sensations of chilliness in extremities and back, unless kept well covered and in a warm room.

Placed her on the following treatment:

℞. Acid. Sulph. Aromat. . . . ℥ iii.
Quin. Sulph. . . . . ʒ ii.
Aquæ . . . . . ℥ ii.
M.

S. Put 2 teaspoonfuls in half a pint of warm water and wash the body and limbs all over every day, and wipe dry after.

After the bath to be pounded all over with a hair ball for 10 minutes, and rubbed afterward thoroughly with the bare hand, till the surface "was in a glow.'

℞. Potass. Iodid. . . . . ʒ iv.
Tr. Cinchonæ comp. . . . . ℥ v.
Tr. Gentian. comp. . . . . ℥ i.
Wine Colchicum (seeds) . . . ʒ i.
M.

S. Take a teaspoonful before each meal.

℞. Acid. Hydrochlor. dil. . . . ℥ iii.

S. Take 10 drops in a glass of water, 10 minutes after breakfast and dinner.

℞. Quin. Sulph. . . . . ʒ i.
Ferri Lactat. . . . . ʒ ss.
Strychnin. Hydrochlorate . . gr. ¼.
Ext. Gentian.
Syrup, āā q. s.
M. Make pills 40.

S. Take a pill 2 hours after each meal.

℞. Pil. Aloes et Myrrh. } XX
U. S. D.—S. C. }

S. Take one on retiring.

Avoid all sweets and organic acids.

To eat rare beef, milk, the yolks of eggs soft boiled, with a little bread and potato.

During a portion of the time she has used the nitro-muriatic acid bath in place of the one before mentioned.

Under this treatment she has slowly but steadily improved. She is still under treatment; and is improving more rapidly than at any previous time.

The blood and secretions are almost free from stelline and stellurine. As these bodies become less and less, her strength and muscular endurance gradually improve.

I should have stated, that for several years before the labor, she had a tired feeling frequently, with occasional attacks of dizziness. These gradually increased in severity and frequency up to the time of delivery.

Case II.—Mr. E. R., of Maumee City. Age, eighteen. Appetite, appearance, and general health good. Does not know when to stop eating. Eats anything set before him. Has a severe attack of *stellurinemia* and *conchoidemia*. Has lost almost entirely his will power. This almost total loss of will extends back for about twelve months. Previous to that time—for several years—he was troubled with fits of despondency and bewildering sensations in head. Was fearful that something dreadful would happen to him. Was, however, able to attend to business up to about fourteen months since. He came under my care in September, 1867. When I first saw him, he was in the condition he had been for some ten months.

He perfectly understood all that was said to him—would smile when anything laughable occurred, memory good, and manifested a disposition to follow directions strictly, but was unable to answer questions, or even to say yes and no, unless excited. If he saw a horse running away, or cars coming, or a house on fire, he could talk as well as any one, apparently. As soon, however, as the excitement ceased, his will power left him, and with it the power of speech. If directed to go across the room and get a book, he perhaps would rise from his chair, and, unless told to go ahead, would stand by the chair till he was directed to proceed or sit down. Sometimes he would get half-way across the room, and stop and stand still till told to go on. In eating, he had to have his food placed on his plate, and unless told to proceed at every mouthful, he would stop and sit motionless till his elbow was jogged, or his will assisted by the direction of a second party.

On examining his blood, found it to contain numerous crystals of stellurine (*e, f, g, h, i, k*) and conchoidine, represented at *o* and *s*.

His blood was otherwise quite normal, save that here and there were small emboli (*k* and *s*).

Placed him on the following treatment:—

℞. Potass. Bromid. . . . . ℥ iss.
Tr. Cinchonæ comp. . . . . ℥ vi.
Tr. Gentian. comp. . . . . ℥ i.
Aquæ Camphor . . . . . ℥ i.
Aquæ Menth. Pip. . . . . ℥ i.
Wine Colchicum (seeds) . . . ʒ i.

S. Take a teaspoonful before each meal, and on retiring.

℞. Acid. Hydrochlor. dil. . . ℥ iii.

S. Take 10 drops in a glass of water after breakfast and dinner.

℞. Acid. Nitromuriat. dil. . . . ℥ iv.
Quinin. Sulph. . . . . ʒ ii.

S. Put 1½ teaspoonfuls in half a pint of warm water, and wash the body and limbs all over every night, and wipe dry after.

℞. Tr. Iodine . . . . . ℥ iss.

S. Paint on each side along the whole length of the spine every other morning.

Avoid sweets and organic acids. Live on rare beef, oyster soup, the yolks of soft-boiled eggs, beef tea, milk, and a little bread and potato. Avoid all stimulants.

Nov. 7th, found him considerably improved. He could answer questions part of the time by using a little effort, and could quite readily say yes and no when asked direct questions. Continued treatment.

I should here say that all the organs of the body appear quite healthy. The heart-beat is rather weaker and slower than normal. In his habits he has always been very correct—is intelligent and strictly moral—he being a conscientious member of church. So far as I can learn from him and his family, and discover from my own observations, he is not troubled with seminal emissions.

Case III.—Mr. A. W. P., Cleveland, Ohio. Called on me in October, 1865. Has always been, up to the period of this trouble, a very strong, robust man, of remarkable endurance. His habits of life active, and labors severe. Age forty-two. Has *stellinemia* and *oxalemia*. For a few days previous to his first visit he had been laboring under temporary aberration of mind. Was perfectly sane when I first saw him; but was laboring under great depression of spirits, and was fearful he was becoming insane. His family were making arrangements to take him to the asylum at Newburgh, but at my solicitation desisted, and placed him in my hands for medical treatment. On working up his case, found it to be one of *stellinemia* and *oxalemia*. Blood filled with masses of granules of oxalate of lime and a multitude of well-defined crystals of stelline.

Urine loaded with crystals of oxalate of lime, both dumb-bell and octohedral—also contained crystals of stelline. Sp. grav. 1.030 to 1.035.

He also had severe nasal catarrh. The catarrhal secretions were filled with crystals of stelline, oxalate of lime, and an algoid vegetation (*zymotosis catarrhalis*). Bowels constipated and portal system congested. Heart sounds normal, but pulsations slow and intermittent, or irregular. Great want of tonicity in muscles of organic life; a tendency to paralysis. Had prickling, numb sensations in extremities, and a dizzy, mixed-up, confused feeling in head, with partial loss of memory. Sometimes he suffered terribly with severe pains in front part of head, accompanied by a feeling of stricture, as if the head were in a vice.

The following is a brief but graphic description of some of the more prominent symptoms, given by himself:—

"In the month of April, 1864, my health failed. The first intimation I had that anything was wrong with me, my mind failed to work; that is, I could not figure correctly, was confused, could not collect my thoughts, or express them intelligently. There seemed to be a heavy weight upon my head—a heavy pressure about the brain. By ceasing to labor, would be better for a little time; but as soon as I commenced again this pressure and confusion would return, and with it a terrible depression of spirits. I could not get rid of the idea that everything was going to fail—country and all were going to ruin. I changed my occupation, hoping to get relief, but continued to grow worse until the fall of 1865. At this time I would have spells, lasting several weeks, of unceasing pain and pressure in my head—not sleeping any for weeks together—and occasionally would lose myself, or not be conscious what I was doing, for from a few hours to two or three days, and would sometimes wander off. At such times my hands and feet would become cold, numb, and almost lifeless. The sensation I had in my head I cannot describe better than to say it was like that produced by

putting the head into a vice, and continuing the tightening operation until sensation ceased (numb and dead). At other times there was a continual noise in it, and any little sudden sound would alarm me. I was in continual fear, and could not tell why. Had a continual dread of seeing any one, especially if I had to converse with him; for it seemed to me impossible to arrange my thoughts and express them in words so as to be understood. When this pressure was gone, I would feel as well as ever, only would be weak, suffering so long from pain.

"In the fall of 1865 I commenced taking medicine ordered by Dr. Salisbury, and in four weeks' time was able to resume my occupation, and was able to follow it through the winter. Ceased taking medicine and did not follow the doctor's directions, and in the month of May, 1866, was taken worse again, and continued so through the summer. Was compelled to seek medical advice again in the month of October. Followed his directions to the letter for seven months, and then, with the doctor's consent, commenced business again, which I have steadily followed since. I am now feeling perfectly well. A. W. P.

"July 25th, 1867."

This case had been diagnosed, previous to my examination, as one of brain-softening. Placed him on the following treatment:—

℞. Acid. Nitromuriat. dil. . ℥ vi.

S. Put a teaspoonful in half a pint of warm water, and wash the body and limbs all over every night, and wipe dry after.

℞. Potass. Iodid. . . . . ʒ viss.
Tr. Cinchonæ comp. . . ℥ v.
Wine Colchicum (seeds) . ℥ i.
Tr. Gentian. comp. . . . ʒ i.

S. Take a teaspoonful before each meal.

℞. Tr. Iodine . . . . . ℥ iss.
Camel's-hair brush.

S. Paint the whole length of the spine and over the heart every other day.

℞. Pil. Hydrarg. Prot-Iodid.
¼ gr. sc. . . . . xxx.

S. Take a pill two hours after breakfast and dinner.

℞. Potass. Acet. . . . . ℥ ii.
" Nit. . . . . ℥ ss.
Spts. Nit. dulc. . . . . ℥ i.
Aq. Menth. Pip. . . . . ℥ vii.

S. Take a tablespoonful in a glass of water at night on retiring.

Under this treatment, after the first two weeks he improved rapidly. After about four weeks' treatment, he visited Kelly's Island and ate grapes freely. Remained a week or ten days on the island, gaining fifteen pounds in weight.

Saw him after this every four weeks. Continued treatment for three months, when he thought himself well enough to stop treatment, which he did against my advice. From January to May, 1866, he remained quite well, and engaged in active business. In May he was again taken down, and confined to his house and bed for about six weeks. His symptoms were intense suffering and pressure in head, producing great prostration and despondency, like those previously described.

The last of June he came again for treatment, and went to work taking his medicines in earnest. Remained two weeks, and then went to Kelly's Island, where he remained four weeks, improving rapidly. He then returned home and engaged in business. In November following gave himself up to treatment, which he has pursued faithfully to this date, July 25th, 1867. Calls himself well, and is able to attend to any kind of business. There is, however, a small quantity of stelline and oxalate of lime in the blood and secretions, for which reason he still continues treatment.

ANOMALOUS CASE OF LABOR.

By WILLIAM J. BURGE, M.D.,
of Atchison, Kansas.

On the morning of Dec. 13, 1867, I was called in consultation with Dr. J. M. Linley, to attend Mrs. W——, æt. about forty, in her eighth confinement. She had been in labor since noon of the 12th, soon after which time another physician had visited her and detected prolapsus of the funis, and one of the feet presenting. Owing to other engagements, he declined to take charge of the case, and directed the woman to send for somebody else. At midnight she commenced flooding, and sent for Dr. Linley, who administered free doses of ergot; and by the ordinary examination discovered the prolapsed cord, which had ceased to pulsate, and a foot presenting. There were no pains of any consequence, and as the hæmorrhage had nearly stopped, Dr. Linley waited about two hours for the action of the ergot, giving repeated doses of the fluid extract and also of the powder.

At the end of this time there were slight pains, and still some hæmorrhage, and I was sent for in consultation. On examination, I found the same state of things above mentioned; and being requested to try and bring down the other foot, I introduced my hand and satisfied myself that the left foot was presenting. I then felt a portion of the placenta, and in close proximity to it what I supposed to be the right tuber ischii, but soon recognised as the head (vertex).

Dr. Linley then examined, and assured himself of the correctness of my diagnosis in every particular. The woman resisted every effort to change the position of affairs. We concluded to put her under chloroform and endeavor to turn and deliver, or to return the foot. There was much delay in obtaining the consent of the family. In the meantime the pains came on more actively, and a second examination convinced us that the head and foot were advancing in the same relative position, and with every probability of becoming impacted. Warning the friends against longer delay, and getting permission to do as we thought best, we sent for chloroform and instruments necessary for extraction. About an hour passed before the messenger returned, and during that time, to our surprise and gratification, the foot and placenta gradually receded, the head advanced, and spontaneous delivery was effected without an untoward symptom. The woman had a capacious pelvis, and had borne seven healthy children. This child was well developed, but was sacrificed by pressure upon the cord.

Cazeaux relates a case of similar presentation (with the exception of placenta prævia) in which embryotomy had to be performed.

Air and Water Pads for Fractures.—Christopher S. Jeaffreson, M.R.C.S., has figured in the *Lancet* an apparatus for the treatment of fractures, which is not only simple and efficient but cheap. The main feature consists in the use of air and water pads formed of india-rubber bags, which are accurately adapted to the insides of the coaptation splints. The great advantage of this contrivance is the establishment of well-regulated and equable pressure, as well as that of cleanliness, over the employment of the ordinary compresses.

INHALATION OF SPRAY OF TINCT. FERRI CHLORIDI IN TRAUMATIC PULMONARY HEMORRHAGE.

By GEO. M. STERNBERG, M.D.,

BREVET MAJOR AND ASSISTANT SURGEON U. S. A., FORT RILEY, KANSAS.

The following case presents some points of interest, and illustrates one of the uses of Richardson's spray apparatus.

Mr. W., a merchant, aged 28, while attempting to put a drunken man out of his store, received a stab in the neck, inflicted by a long, narrow-bladed butcher's knife. The knife entered the neck on the right side two and one-half inches above the clavicle, and just to the right of the common carotid artery, cutting the anterior jugular vein, and passing downward and backward into the lung.

The bleeding from the vein was free, but a bystander controlled it by pressure with his thumb, and it did not recur.

Mr. W. at once commenced coughing and expectorating bright red blood, filled with minute bubbles of air. From this time until I was called (about eighteen hours) he continued to cough up every few minutes a mouthful of blood.

When he was first wounded he sent for a hospital steward of the army, with whom he was acquainted. The steward probed the wound, and stated that the œsophagus was wounded. I presume his diagnosis of the case was founded upon the facts that blood came from the mouth, and that any attempt to swallow the medicine he gave produced a violent paroxysm of coughing. The steward prescribed tinct. ergot with a view of controlling the hæmorrhage, and injections of beef tea and brandy to keep up the pulse. As the hæmorrhage continued and the man was rapidly becoming exhausted, his friends became alarmed and sent for me. After seeing the case, I at once sent for my Richardson's spray producer and some tinct. ferri chlor. The distance was six miles, and it was two hours before my messenger returned. In the meantime Mr. W. continued to cough up a mouthful of blood every few minutes, and the total amount during the two hours could not have been less than sixteen fluid ounces. Perfect rest was enjoined, and no treatment adopted until the spray apparatus arrived. I then added half ounce tinct. ferri chlor. to five ounces of water, and placing the extremity of the instrument well back in the mouth, caused the spray to enter the lungs, by pressing the bulb at each inspiration. This was continued for about a minute, and after an interval of five minutes was again resumed for a minute.

The hæmorrhage was arrested completely, and did not recur. About twenty minutes after a hypodermic injection of morph. sulph. gr. ¼ was administered, and in a very short time the patient fell into a quiet sleep. I remained with him all night. He occasionally woke up for a moment and then dropped asleep again. The next morning he commenced to cough up occasionally a little dark clotted blood, evidently a part of the clot formed by the action of the tinct. ferri chlor.

Perfect rest was enjoined, and injections of beef tea and brandy were administered from time to time during the next twenty-four hours. The following day he was able to swallow a little wine and beef tea, and in addition to the small clots of dark blood, a little muco-pus was expectorated.

He continued rapidly to improve, the external wound healing by first intention, and there being no inflammation of the lung beyond the immediate vicinity of the wound. He is now (nine days after the injury) able to sit up in his bed, and attend to some business.

He lost his voice entirely from the moment he was wounded, and has not yet regained it. He can only swallow liquids, in small quantities at a time, and then by an effort and using great care, as there is a disposition for them to pass into the larynx, producing violent paroxysms of coughing.

These phenomena are probably due to section of the recurrent laryngeal nerve, or some of its branches.

Original Lectures.

LECTURES UPON THE PHYSICAL EXPLORATION OF THE ABDOMEN.

DELIVERED IN THE PRELIMINARY COURSE AT THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF NEW YORK.

By ALFRED L. LOOMIS, M.D.,

PROFESSOR OF INSTITUTES AND PRACTICE OF MEDICINE.

Lecture III.

Physical Examination of the Kidneys, Bladder, Uterus, and Ovaries. Rules for Performing Uterine Auscultation.

Gentlemen—This morning I will detail to you as briefly as possible rules which may guide you in physical examinations of the kidneys, bladder, uterus, and ovaries. I will commence with the kidneys. The kidneys, as you are aware, in health are situated in the lumbar regions, in the space corresponding to the two last dorsal and the two upper lumbar vertebræ; the right is a little lower than the left. Superficially, they extend from the eleventh rib to the os ilii. The right is bounded above by the posterior and inferior portion of the right lobe of the liver; below, by the cæcum; anteriorly, by the ascending colon; and posteriorly, by the spinal column. The left is bounded above by the spleen, anteriorly and inferiorly by the colon, and posteriorly by the spinal column.

In disease, the kidneys may be increased or diminished in size. Atrophy or diminution in size can hardly be determined by physical examination, so that enlargements are the only conditions to which physical exploration is applicable. The kidneys may be enlarged from calculi, pyelitis, which sometimes converts the kidneys into a bag of pus, cancerous and tubercular deposits, hydatid cysts, and simple distension, the result of obstruction of a ureter. A tumor is also sometimes developed at the upper border of a kidney, from disease of the supra-renal capsule.

Inspection rarely furnishes any evidence of enlargement of a kidney. And not unfrequently after examining the lumbar regions by *palpation* with great care, and by careful comparison of the two sides, we are unable to recognize any change in the size of these organs; but as soon as we place our hand anteriorly and press firmly towards the normal position of the kidney, a tumor is felt; then by pressing the tumor backwards, our other hand resting on the lumbar region of the same side, we at once determine that this tumor has its origin in the kidney. The part of the abdomen in which a renal tumor is felt will vary according to the nature of the disease, and the portion of the kidney involved.

Percussion.—In percussing the kidneys, auscultatory

percussions should be employed; the patient should be placed on the abdomen and chest, which position will allow fluid accumulations in the abdominal cavity to gravitate forwards, and the intestines to float upwards. The external margin of the kidneys can then be readily determined by the tympanitic note of the intestines around their circumference, except where they are in relation with vertebræ. In *health*, the outlines of the renal dulness will correspond to the limits already given. Any enlargement of these organs will cause a corresponding increase in the area of renal dulness; but we cannot by physical examination establish the exact nature of the disease to which the increase in the organ is due.

The sources of error in the diagnosis of enlargements of the kidneys vary according as the right or left kidney is the seat of disease.

Enlargement of the right kidney may be mistaken for an enlargement of the right lobe of the liver, for cancer of the pyloric orifice of the stomach, for fæcal distension of the colon, and for enlargement of the right ovary. The rules for distinguishing it from each of these have been already given in a previous lecture, as likewise for distinguishing enlargements of the left kidney from enlargement of the spleen, the left ovary, and from fæcal distension of the descending colon.

Bladder.—When the bladder is empty its position cannot be determined by physical exploration; it can only be detected when it is distended, and rises above the pubes; when this is the case, a tumor is visible in the hypogastric region, which on palpation is smooth and oval. Its circular margin is easily made out by observing the tympanitic sound of the intestines on the one hand, and the dull sound produced by the bladder on the other. In infants, the bladder is not as deep in the pelvis as in adults, consequently a smaller quantity of urine in the bladder can be recognized. A distended bladder can only be mistaken in the female for a gravid uterus, or a uterine tumor; the use of a catheter removes all doubts.

Uterus.—The unimpregnated uterus in its normal state is situated in the lower part of the hypogastrium, and is inaccessible to the touch (externally), or to percussion; but when normally developed by impregnation, or abnormally by disease, palpation, percussion, and auscultation, furnish us with important information.

In pregnancy, at the end of the second month, a dull sound on percussion, just above the pubes, indicates the development of the uterus; later, as the uterus increases in volume, and rises into the abdomen, we are able, by the oval tumor felt in the hypogastrium, and by the circumscribed area of dulness corresponding to the situation of the tumor, to establish strong presumptive evidence of pregnancy. The presumption becomes strengthened if the area of the dulness increases with the regularity proper to gestation. But percussion and palpation are insufficient to determine whether the development of the uterus is due to pregnancy, or to some morbid deposit in its walls or cavity, as fibrous tumors, etc.

At the end of the fifth month, the evidence furnished by both these methods is inferior to auscultation.

Rules for performing Uterine Auscultation.—The patient should be placed on her back, with her thighs slightly flexed, so as to relax the abdominal muscles; sometimes it is well to incline the body from one side to the other, or forwards so as to withdraw the pressure of the uterus from the pelvic arteries. The abdomen should be uncovered; as the sounds to be examined are of slight intensity, and very circumscribed, their study demands close attention and perfect silence. The stethoscope is always to be preferred, and the uterine tumor should be auscultated successively at different points.

After the fourth month of gestation, if the uterus contains a living fœtus, we may hear three distinct sounds: the *placental bruit*, which is evidently connected with the circulation of the mother; *the fœtal heart*, and the *funic souffle*, which are connected with the circulation of the fœtus.

Placental Bruit.—This sound is single, intermitting, and in character is a combination of the blowing and hissing sound; it increases in intensity up to the period of labor. It is believed to depend upon the rapid passage of blood from the arteries into the distended venous sinuses. It is synchronous with the maternal pulse, is subject to the same variations, and is always heard before the pulsation of the fœtal heart.

The *area* over which it is audible varies. In some instances it is limited to a single point, in others it is audible over a surface of three or four inches, and in a few it is heard over the whole uterine tumor; although there will always be one spot of greatest intensity, corresponding to the placental attachment. It is also intensified by uterine contractions.

During the first half of pregnancy, it is usually heard with greatest intensity in the median line, a little above the pubes; after the fifth month at the lateral and inferior borders of the uterus, and next in order of time it will be heard at the fundus.

This sound may be confounded with the respiratory murmur of the mother, and with intestinal murmurs; these murmurs, however, are not synchronous with the pulse of the mother; and if this fact is remembered, there will be little difficulty in distinguishing them. As a proof of pregnancy, placental bruit is not positive, as it is sometimes heard in connection with uterine and ovarian tumors. It does not prove that the fœtus is alive, for it is heard for a time after its death. Its negative evidence is of less value; for if the placenta is attached posteriorly, we may not be able to hear it, although pregnancy exist.

Funic Souffle.—This sound is usually heard at a point quite remote from the placental bruit; it is short, feeble, and blowing in character, and corresponds in frequency with the fœtal pulsation. It is supposed to depend upon obstruction to the transmission of blood through the umbilical arteries, as from twisting or knotting of the funis, or from external pressure; it is not a constant nor even a frequent sound; the conditions which produce it are rarely met with.

Fœtal Heart Sound.—This sound consists of a succession of short, rapid, double pulsations, varying in frequency from 120 to 140 per minute. The first sound is short, feeble, and obscure, while the second (the one we usually hear) is loud and distinct, and may be heard over the body and limbs of the child. This sound has been aptly compared to the ticking of a watch wrapped in a napkin, and is usually first heard at the middle of the fourth month. The frequency of the pulsations does not vary with the age of the fœtus. The extent over which the fœtal heart sound is audible varies; usually it is transmitted over a space three or four inches square. The location of the sound is determined by the position of the fœtus. It has been stated that by drawing a horizontal line, and dividing the uterus into two equal parts, whenever the maximum of intensity of the sound is below this line, it is a vertex presentation; when above it, a breech; also when the fœtal pulsations are heard low down in front on the left side, that the fœtus is in the first position (R. O. I.); if heard below, and in front on the right side, it is in the second position (L. O. I).

Twin pregnancy may sometimes be determined by

the presence of heart sounds heard at distant points over the uterine tumor, and by the absence of synchronism in the two pulsations. The sources of deception in exploring for the fœtal heart sound are the liability of confounding the pulsations of the iliac or abdominal arteries of the mother with it; in most cases their situation, comparative frequency, and absence of double pulsation, will determine their character. But a difficulty will sometimes occur in discriminating between them when the maternal pulse is very much increased in frequency, and the fœtal diminished. Under such circumstances we must be guided by the character of the sound; and if it is or is not synchronous with the radial pulse.

Again, in the early stage of pregnancy, the intensity and impulse of the maternal pulsation may render the feeble fœtal sound inaudible; changing the position of the fœtus, and thus removing the pressure of the uterine tumor from the subadjacent arteries, will obviate this difficulty. During labor our examination should be made in the interval between uterine contractions. In protracted labors auscultation is of value in indicating to us the time for manual or instrumental interference, in order to save the life of the child. The indications of danger to the child are feebleness or excessive frequency of the fœtal pulsation, irregularity in its rhythm, absence of the second sound, its complete cessation during uterine contraction, and the slowness of its return in the interval; irregularity and feebleness are the most threatening to the life of the child. When the sound of the fœtal heart is heard, it is always a proof of pregnancy, but its absence is not positive evidence that pregnancy does not exist; for the fœtus may be dead, and in some rare cases the sounds may exist and be quite inaudible for a time, and then appear. This phenomenon is not easily accounted for.

Tumors of the uterus, whether developed on its surface, in its walls, or within its cavity, give rise to enlargements of the organ, which cause it to occupy a position corresponding to that occupied by a gravid uterus. The position and extent of these enlargements are determined in the same manner as we determine the size and position of the uterus in pregnancy. Deposits in its walls or on its surface give rise to nodules, which feel through the abdominal walls like hard balls, varying in size and shape, seldom occurring singly. The whole mass can usually be moved from one side to the other. The connection of these tumors with the uterus, as determined by the uterine sound, leaves little doubt as to their true character; and by this means we readily distinguish them from all other abdominal tumors.

Ovaries.—The ovaries in a normal state lie in the pelvic cavity, and their position cannot be determined by physical exploration; but when they become the seat of those forms of disease which cause their enlargement, and have attained such dimensions that there is no longer room for them in the pelvic cavity, they ascend above the brim of the pelvis, and occupy more or less space among the abdominal organs. As they pass out of the pelvis they are first noticed in the right or left inguinal region, according as the right or left ovary is affected, and they are then recognized as ovarian tumors. Often, before these ovarian enlargements have attained sufficient size to attract the attention of the patient, they will have reached a central position in the abdominal cavity. They are of more frequent occurrence than all other forms of abdominal tumors, and their existence is determined almost exclusively by the physical signs which they furnish.

Inspection.—In the early part of their development an uneven projection or prominence of one part of the abdomen will disclose the seat of the tumor, occupying usually the iliac or lumbar region of one side, and extending upward to or beyond the umbilicus; while in more advanced cases no irregularity will be visible, but the rounded form of the abdomen (while the patient lies on her back) offers a strong contrast to the flattened oval appearance of ascites, or the central rounded form of a uterus distended by pregnancy.

Palpation.—Ovarian tumors, when small, have a firm, elastic feel; but when large, they are soft and fluctuating. In some cases, by passing the hand gently over the abdomen, the extent of the tumor will be readily appreciated. At other times, the limits of the tumor cannot be ascertained by gentle palpation, for it occupies the whole of the abdomen, except the concavity of the diaphragm. In such cases, by making firm but not forcible pressure on various parts of the abdomen, we often detect at once a general sense of fluctuation, and ascertain inequalities which neither the eye nor the hand, when passed gently over the surface, will enable us to detect; and sometimes if the abdomen is not tense, we can feel masses which convey the impression of more or less flattened or spherical bodies attached to the inside of a fluctuating tumor. In some cases, the sense of fluctuation is very indistinct; in others it is even more evident than in cases of extensive ascites.

Percussion.—The sound elicited on percussion is flat over that portion of the abdomen where the tumor comes in contact with the interior surface of the abdominal wall; while at the side, and above where the intestines have been pushed aside and upwards by the tumor, the percussion sound will be tympanitic; by this change in the percussion sound we are enabled to mark out the boundaries of the tumor.

Differential Diagnosis.—Ovarian tumors may be confounded in their diagnosis with *uterine enlargements* (as pregnancy, fibroid tumors of the uterus, etc.), *ascites*, *hydatids of the omentum*, *fœcal accumulations in the intestines*, and *enlargements* of the *liver*, *spleen*, and *kidney*.

They are distinguished from pregnancy by a stethoscopic examination of the tumor, which reveals in the one case the sounds of the fœtal heart, and in the other their absence. They are distinguished from uterine tumors by their different consistency, by the difference in their outline, by the difference in their connection and relative position to the uterus, and by the fact that in uterine tumors the cavity of the uterus, as determined by the uterine sound, is always elongated. The diagnosis between ovarian and abdominal dropsy is made: 1st, by observing the difference in the shape of the abdomen when the patient lies on her back; ovarian tumors project forward in the centre, while in ascites the abdominal enlargement is uniform. 2d. In ovarian tumors the percussion sound is dull as high as the tumor extends, while at the same time there will be tympanitic resonance in the most depending portion of the abdominal cavity; in ascites the most depending portion of the abdomen is always flat, the percussion resonance being confined to the epigastric and umbilical region. 3d. In ovarian dropsy the relative line of flatness and resonance is not altered by change in the position of the patient, which is not the case in ascites. Hydatids of the omentum form a class of tumors which you will be unable by physical signs to distinguish from ovarian tumors. The fact, however, that these omental enlargements are first noticed above the umbilicus, and gradually enlarge downwards, while ovarian are first noticed low down in the abdomen, and gradually enlarge upwards, will in most cases be sufficient for a diagnosis.

Fæcal accumulations in the large intestines may be mistaken for ovarian tumors; the peculiar feel of such tumors (which has already been described) will, however, enable you to distinguish them from ovarian tumors.

Reports of Hospitals.

BELLEVUE HOSPITAL.

FRACTURE AT THE BASE OF THE BRAIN.

EXTENSIVE CENTRIC APOPLEXY; ANOMALOUS CONDITION OF PUPILS.

REPORTED BY CHARLES S. BULL, M.D., SENIOR ASSISTANT PHYSICIAN.

SERVICE OF DR. MCCREADY.

HENRY DE TOUR, aged sixty, married, a native of Canada, and by occupation an engineer, was admitted to Ward 14 of the Bellevue Hospital, Nov. 2, 1867, at 10 A.M. No history or facts of any kind were brought with the patient relative to his physical condition. He had been a night-watchman at the Academy of Music, and was found, early in the morning of admission, in an insensible condition.

On admission, the patient was comatose; his breathing was stertorous, his pulse 116 in the minute, and very feeble. His tongue was moist and slightly coated, and the surface of the body was cool. The right pupil was dilated, the left one contracted. There was some œdema of the lower extremities; and this, in connection with his comatose condition, had caused him to be sent to the medical side of the hospital, as a case of uræmic coma.

His wife stated that for some time back he had suffered from nausea and vomiting, and frontal headache, and she gave a pretty clear history of Bright's disease.

About a year ago he had been attacked with a convulsion, from which he soon recovered, and he had had none since.

Over the right temple was a large tumor, about the size of a small orange, bluish-black in color, and having three small cuts on its surface, none of which extended through the integument. The patient was grinding his teeth, and exhibited tonic contraction of the muscles of the extremities.

The urine, on examination, revealed albumen and hyaline, and granular casts. A diagnosis was made of coma from uræmic poisoning, and olei crotonis gtt. iij. were administered, but without the desired result, and the dose was repeated. The hot-air bath was then tried, in hopes of bringing on diaphoresis, but failed utterly; and notwithstanding all the means employed for his relief, the patient sank, and died at half-past three P.M. of the same day, the stertorous respiration and coma having continued until the last.

Autopsy eighteen hours after death. Rigor mortis well marked. On cutting into the tissues of the scalp, they were found to be infiltrated with blood. On separating the scalp from the pericranium, a large collection of coagulated blood was found beneath the tendon of the occipito-frontalis muscle, just under the point of external swelling. The temporal and occipital arteries of the right side were both ruptured, and their lacerated extremities could be dissected out amid the tissues of the scalp. No point of fracture could be detected over any portion of the vault of the cranium.

On removing the calvarium, the dura mater was found to be intensely congested, and a large amount of fluid blood was found between this membrane and the skull. There were no signs of inflammation to be detected. There was also considerable blood extravasated in the subarachnoid space. The brain was very much softened, so as to be removed with great difficulty. It was very much congested, and from the amount of blood found beneath the anterior lobes of the cerebrum, it was supposed that the anterior cerebral arteries had been ruptured. The arteries of the brain were to all appearances healthy, no atheroma having been discovered. On slicing open the brain, the entire right hemisphere of the cerebrum was found to be hollowed out; the brain substance apparently gone, as no trace of it could be found, and its place occupied by an immense clot of blood, filling all three of the lobes. A smaller clot, about the size of a pigeon's egg, was found occupying the anterior lobe of the left hemisphere.

An examination of the base of the skull revealed a stellated fracture of the petrous portion of the right temporal bone, commencing just over the internal ear, and extending about half an inch in various directions; but it did not reach across the median line.

The contents of the thorax were in a healthy condition. The abdominal organs were normal, with the exception of the kidneys. These were of the small, fibrous, contracted variety, weighing but five ounces together. The cortical portion had nearly entirely disappeared in both, and the left one contained a few small cysts.

The case presents several points of interest, which are as follows: 1st. From the presence of the clots, both pupils should have been dilated, whereas the left one was firmly contracted. 2d. Was the fracture found at the base of the skull produced by a fall while the patient was in a uræmic convulsion, or was it the result of a blow? 3d. The presence of a fracture at the base, while no lesion could be found in the vault.

Progress of Medical Science.

FIFTY-ONE CASES OF OVARIOTOMY.—Thomas Keith, F.R.C.S., gives in a recent number of the *Lancet* a tabulated statement of fifty-one cases of ovariotomy which he has performed, of which the following is a summary:

Of 51 operations, there were 40 recoveries and 11 deaths. The average duration of the disease was a little more than two years, and 28 had been tapped once or oftener before the operation. The youngest was 16, the eldest 68 years of age; 26 were married, 25 unmarried. Under 22 and above 52, all recovered. Of 16 above 45, all recovered save one. Of 5 cases in which both ovaries were removed, 4 recovered. The average weight of the tumors was 34 lbs.; that of the fatal cases 42 lbs. The smallest was a semi-solid mass of 7 lbs., in a case where a large cyst had burst a fortnight before. The largest was upwards of 120 lbs. A great part of it had to be dissected out. Its removal was the most formidable proceeding he was ever concerned in, and it is, so far as he was aware, the largest tumor ever removed successfully from the living body. Adhesions, if not in the pelvis, do not seem to him to influence much the result of ovariotomy. In the cases of single, or nearly single, unattached cysts, nothing could be simpler than the operation, and in several the cicatrix is now not more noticeable than the umbilicus. The majority, however, were extremely severe operations—in not a few extending over two hours; and the recovery of many was very remarkable. Only three were absolutely

unilocular cysts. In 9 cases the tumor was throughout semi-solid. All of these recovered save one. These tumors were cut into and broken up by the hand, and removed through as small an incision as possible.

Removing Particles of Foreign Matter from Eye.—Dr. E. M. Moore recently informed me of a method for removing particles of foreign matter from the conjunctival fold in cases where other means seem insufficient. It consists in scarifying the lid in the usual way, then closing the eye and allowing the blood to coagulate and entangle the irritating substances in the clot. When the latter is removed it brings away the foreign particles with it. This process was, I believe, originated and frequently practised by the late Dr. Munn, who, a few years ago, had a great reputation for skill and tact in the management of eye diseases.—Dr. C. E. Rider, *Rochester, N. Y.*

Mental Medicine.—At the meeting of the Academy of Medicine, September 17, 1867 (*Gaz. Hebdom.*), Dr. Lisle read a note upon the treatment of cerebral congestion and hallucination by arsenious acid. The conclusions of his paper are the following: "The insane often present symptoms of cerebral congestion. This is always the case with those laboring under hallucinations. Of one hundred and ninety-three of the latter, treated by arsenious acid, one hundred and thirty-one, or sixty-seven per cent., were cured, and twenty-seven experienced a marked and permanent improvement. Hallucination, hitherto considered as a symptom of insanity, is simply a complication nearly always grave. It is the most characteristic symptom of cerebral congestion. Arsenious acid is a remedy really specific in the disease. It is also very useful in cases of paralysis, incoherency, melancholia, etc., free from hallucinations, but presenting the evident signs of cerebral congestion. Arsenious acid, administered with prudence and watched with care, is one of the most inoffensive agents of the materia medica. The dose varies from five to sixteen milligrammes (one-thirteenth to one-quarter grain) administered three times a day at the beginning of each meal."

Large Aneurism of Femoral Treated Successfully by Compression of the Aorta.—Mr. Geo. Lawson (*Lancet*) reports a case of the above which occurred at the Middlesex Hospital. The patient was a stableman, thirty-six years of age, otherwise in good health. At first a Carte's compressor was applied to the femoral, but no cure resulting a resort was had to the compression of the aorta by Lister's compressor. The operation and its result are thus described:

On October 10th, at three o'clock P. M. (the bowels having been completely emptied by an enema), the man was placed thoroughly under the influence of chloroform. A Lister's tourniquet was applied over the abdominal aorta just above the umbilicus, and another tourniquet was placed firmly over the femoral artery just below the aneurism. Mr. Moore took charge of the tourniquet over the aorta, whilst Mr. Lawson kept his finger on the artery just above the aneurism, to watch if any blood passed into the tumor. The tourniquets were kept on for twenty-three minutes; only once at the end of the fourth minute did a wave of blood pass into the sac of the aneurism, when the tourniquet over the aorta was at once tightened; but for the remaining nineteen minutes absolute compression of the vessel was maintained, and no blood entered the tumor. The man became now somewhat collapsed, and began to retch. The tourniquets were then removed and the administration of the chloroform stopped. The pulsations in the tumor were diminished, but they were perfectly regular. It was, however, impossible to say whether the diminution of the pulsations were not due to the collapsed state of the patient. The man was returned to his bed, and the Carte's compressor readjusted over the artery. When the effects of the chloroform had completely passed off, he complained of coldness and numbness of the legs, with soreness in the belly. At seven o'clock in the evening, finding that all pulsation had ceased in the aneurism, the man himself removed the compressor. The house-surgeon was at once sent for, and he found that there was no longer any pulsation in the tumor. Since that time the man has continued to improve. With the exception of some feeling of soreness in the belly, which lasted for about thirty-six hours, the patient suffered no inconvenience from the treatment. October 17th.—The aneurismal sac is now felt as a hard oval mass; the artery which leads to it pulsates strongly, but all impulse ceases at the upper edge of the tumor.

Treatment of Scarlatina, by Dr. Dyes.—According to Dr. Dyes, the course of scarlatina depends entirely upon the intensity of the inflammation of the throat accompanying the exanthema, and which, being identical with diphtheritis, requires the same treatment as does the latter. He recommends chlorine water as the only effectual means to the end desired, and claims to have had abundant opportunity of convincing himself thereof in one hundred and sixty-three successful cases of diphtheritis, and five of scarlatina, in all of which the remedy was employed within the first five days of the disease. When gangrene had commenced, which is usually on the sixth or seventh day, the results were less favorable. The use of gargles of borax, alum, etc., is pronounced utterly valueless, as also the administration of chlorate of potassa, which, moreover, is always given in far too small doses. The author gives children under three years old the chlorine water diluted with one-third its bulk of water, to those between three and seven years old with one part in four of water, and above the age of seven, unadulterated. The frequency of its administration depends on the stage and the severity of the disease. During the first three days of the disease he gives a teaspoonful three or four times a day; afterward, according to circumstances—every two hours, or every hour. It is necessary to guard against the decomposition of the chlorine water. To this end it is essential that the dose be swallowed rapidly, as its efficacy is otherwise decidedly lessened; and also, that no other drink be permitted for some little time after. The author bases the efficacy of this method on the antiseptic and anti-miasmatic qualities of the chlorine, whereby the spores of a peculiar species of plant from which the diphtheria is developed, are destroyed. He also recommends the taking of small doses of chlorine water daily, as a prophylactic by those exposed to the infection of scarlatina.—*Deutsche Klinik*, 1867, *No.* 7.—*Zeitschrift für Medicin, etc.*

Concerning the Possibility of Galvanizing the Brain and Spinal Cord in the Human Subject. By Dr. Erb. (From a paper read before the Medical Natural History Association, at Heidelberg.)—One of the most important questions concerning the application of the galvanic current to therapeutical purposes is that of the practicability of reaching with this current individual portions and organs of the body. The possibility of thus reaching the great centres of the nervous system — the brain and spinal cord — is considered by Remak, Benedikt, Brenner, and others, as a matter of course; whereas, Ziemssen, in the last edition of his work on Electro-Therapeutics, declares himself deci-

dedly of opinion that these nervous centres cannot be reached either by constant or induced currents through any appliances at present employed in therapeutics.

As the settlement of this question is one of no little importance, Dr. Erb undertook a careful investigation of the same, and gives us the following results: As a test, various experiments were tried on the dead body, and they invariably proved that on application to the cranium of even weak, constant, and induced currents, these spread into the substance of the brain with such force as distinctly to contract the muscles of the frog's leg, the nerve whereof was in contact with the brain. One is thus led to the conclusion that it is thoroughly practicable to reach the encephalon through the cranium, with the appliances at present employed, and that in such cases the dizziness, deafness, distress, and faintness induced, are to be regarded as evidence of the direct excitation of the brain. Induced currents penetrate this organ with equal facility, but produce as trifling effects therein as they do on the retina, and other higher nerves of sense. In the spinal cord, where the relations of the superjacent tissues are somewhat different from those of the head, experiments have given the same result, viz. that by the ordinary application of the electrodes to the back, a constant current penetrates to the cord itself. Experiments on the living body leave scarcely room for doubt that by the changing or interruption of these currents a lively excitement is induced in the nerves lying within the spinal canal, and that thus the value of the application of electro-galvanic currents to the spinal cord is established. The author confirms former testimony to the effect that the constant galvanic current is the one to be preferred in treating affections of the great nerve centres.—*Heidelberger Jahrbücher der Literatur*, 1867. *Zeitschrift der Medicin, etc., Leipzig.*

Citrate of Soda in Diabetes.—The *Journal of Medical Chemistry* calls attention to a fact, which if confirmed, will be fruitful of the most important consequences. We refer to the property of citrate of soda, in causing to disappear glucose in diabetic urine. This indeed appears the result, from a good many experiments with the salt. It was administered in the dose of from 4 to 8 grammes a day, mixed with the food, as common salt.

What is its mode of action? It possesses this advantage over the *carbonate* of soda, that it will not interfere with the digestive functions, and it furnishes in a more efficacious manner the alkaline carbonate necessary to the chemical transformation of glucose. The experiments will continue.—*La France Medicale.*

Urachus Pervious after Birth.—Of this Dr. G. J. Townsend relates the following case: "I was asked to see a negro child, five days old, and was told that he was passing his water through his belly. The urine bubbled freely from the umbilicus every time the infant cried or made any great exertion. The cord had separated normally, and the child was in every other respect vigorous and healthy. There was evidently ulceration of the surface, left by the separation of the cord. The urethra was entirely pervious. The ulcerated surface was freely cauterized, and the edges of the opening were brought into close apposition, and kept there by a strip of adhesive plaster firmly applied in a longitudinal direction. This was still further secured by a compress of cord *covered* with wash-leather, and kept in place by being stitched to a closely fitting swathe. The patient was well in four days, when the swathe was removed.—*Boston Med. and Surg. Journal.*

Case of Intermittent Orchitis.—Dr. W. H. Morton reports a case of intermittent fever, to which he was called, and which yielded readily to quinine. In about ten days was again called to see the same patient, who had accidentally bruised his testes. At the time of the visit patient complained of severe pain in the left testis. The organ was hot, tender, and enormously swollen, presenting the ordinary symptoms of acute orchitis. Hot hop fomentations were ordered, the parts were kept elevated, and morphia was administered to quiet the pain. On the following morning the patient was very much better, but the same symptoms returned at the same time the following night, suggesting an intermittent tendency. He was ordered quinin. sulph. one scruple, to be taken during the intermission. The patient had no further paroxysms, and speedily recovered.—*N. Y. Med. Journal.*

Treatment of Intermittent Fever by Chloroform internally.—Six cases of intermittent fever are reported by Dr. Bricket, in the *Chicago Med. Examiner*, which were treated with chloroform, with the happiest results. In some of the cases quinine had been administered, but had not broken up the chills. In each case one drachm of chloroform was given, with the immediate effect of giving a quiet sleep of from 1 to 2 hours, and no further medication became necessary. The cases in which the drug was given were all uncomplicated, and the result was in the highest degree satisfactory. Further trial of chloroform in this disease is recommended.

Chloroform in Pernicious Fever.—In the *Richmond Med. Journal*, Dr. S. Eagon says: "My attention was first directed to chloroform administered internally, in 1860, by Dr. Fenner, of New Orleans, who had, prior to that period, employed it with very gratifying effects in several cases, as well as in the cold stage of ordinary intermittents, with like results. Dr. F. says: 'From the very prompt and happy effects experienced in the limited number of cases in which I have seen the remedy exhibited, I am inclined to regard chloroform, internally administered in the dose of from half a drachm to a drachm, repeated in the interval of 15 or 20 minutes, as possessing more potency than any other article of the materia medica, in bringing about reaction from the frightful collapse of congestive fever.' Having practised since 1860 in a highly malarial district, ample opportunity has presented itself of putting to the test Dr. F.'s assertion as to the value of chloroform in relieving the paroxysm of intermittent fever in the cold stage, and I am happy to be able to add, that in doing so I have had occasion to feel thankful to him for his valuable suggestion. The different medical journals bear testimony to the value of chloroform in intermittents in the cold stage. My own experience accords with the views expressed in these articles. I regard pernicious and intermittent fever as differing in degree only, and not in kind. Of the *modus operandi* of chloroform in relieving the cold stage, I have seen no explanation. It seems most plausible to suppose that a powerfully stimulating impression is produced on the stomach by immediate contact of the remedy, which impression is rapidly conveyed, chiefly through the medium of the nervous system, to the capillaries, exciting in this system of vessels remote sympathy. As to the prophylactic or antiperiodic power of chloroform, in intermittent fever, I am inclined to think it possesses no greater virtue in this way than is common to all narcotics."

Acute Idiopathic Glossitis, by Dr. J. B. Burnett, M.D., Bellevue Hospital.—A patient presented himself at the hospital, who within two months had had several returns of "a lump in the left side of the throat." A

week before admission he attended a picnic, at which he drank freely of lager beer. During the night he slept in a draught between two windows. In the morning his tongue was greatly swollen, hot and painful, and his throat sore, so that he could scarcely articulate or swallow. There was a profuse salivary discharge during the day. By afternoon the tongue almost completely filled the mouth, and greatly impeded respiration. The pain in the tongue was intense, and he was feverish, anxious, and restless. When admitted he presented the following symptoms: tongue swollen and hard, immoderate action of the salivary glands, glands beneath the jaw indurated, fœtor of breath, pulse nearly normal, skin cool, bowels regular, and urine normal. Treatment was gargles of potass. chlorat., ice to tongue, and saline purgatives. Diet, milk and beef tea. In about ten days patient recovered completely.—*Med. and Surg. Reporter.*

Steel Purse Ring Impacted in Naso-Pharyngeal Fossa for Thirteen Years and a Half.—Dr. William Hickman, M.B., F.R.C.S., relates in a recent number of the *British Medical Journal*, an interesting example of the long residence of a foreign body in this cavity. The child was two years old when the accident which resulted in the introduction of the ring occurred. While at play it was suddenly seized with a fit of choking produced by the ring with which the child was at the time nursed, and the mother thrust her finger in the throat, and after having felt it it disappeared, and she supposed it had been swallowed. The patient afterward suffered from symptoms of polypus, and it was only after the time referred to had elapsed that the existence of this foreign body was made out by a careful examination with the rhinoscope. An ineffectual effort was made to push the foreign body down into the mouth by means of an instrument introduced through the nostrils, but on this failing, guided by the history of the case and the appearance of the foreign body, the operator made a hook with a long probe bent into three curves, and passed it up behind the palate; and after some time and considerable trouble, and with the assistance of the forefinger of the left hand, he managed to pass the hook through the ring and bring this away on the probe. The ring was a wide steel one (completely blackened and rough from its lengthy sojourn), which had belonged to one of the old-fashioned long purses; it measured nearly three-fourths of an inch in diameter, and nearly half an inch in width.

Congenital Obstruction of Urethra.—A woman was delivered of a healthy-looking boy, on June 13, and next morning both were doing well. Meconium passing freely. By evening, child had had no urinary passage, but discharges from bowels frequent and thin. Upon examination, found the external meatus urinarius closed, as though it had united by adhesive inflammation, but no distension of urethra. The external orifice was opened with a bistoury, but no urinary discharge. The probe was introduced about four lines, and found obstruction, through which it was forced. The probe was passed four lines further, and another obstruction found, which required considerable force to pass. Finding no tumefaction over the bladder, it was concluded that the serum had passed off by the bowels without being secreted by the kidneys. The probe was carried through still another obstruction to the pubes. The instrument was then bent and passed, as was thought, into the bladder; but no urine followed. Next morning the child passed urine freely, showing that the obstructions had been broken down the night before. Had there been a free secretion of urine, the child must have suffered, and perhaps have died before the forty-eight hours expired, for it had been born that long before any urine was passed. The active condition of the child's bowels had prevented the secretion of urine. The child afterward did well, and had no difficulty in urinating.

An Inquiry into the Effects of Putrefying Organic Substances upon Living Animal Organism.—Dr. Schweninger, of Munich, thus sums up the results of injections into the blood, directly, the experiments being made upon seven dogs and twelve rabbits: "1st, The injection of putrid fibrin into the blood creates an increased temperature—fever. 2d. This symptom appears rapidly after the injection, yet not immediately, and seems sometimes to be preceded by a sinking of the temperature. 3d. The general infection is apparent from the affection of the intestines, disturbed nutrition, and the vehement attack upon the nervous system, tremor, vomiting, and great depression. 4th. The vehemence of the effect depends on the quantity of the fluid injected. 5th. Smaller animals are more affected than larger ones. 6th. The concentration and state of putrefaction are of no influence on the mode of operation of the injection. 7th. The effect is also brought about after fluids had been evaporated to dryness, if the experiment is made with the redissolved dry substance. 8th. The injection of filtered putrid liquids never creates metastases, or abscesses in the different organs of the body. Experiments with putrid gaseous emanations, although the animals were confined for several weeks in rooms highly impregnated with the same, produced no kind of morbid affections."

"If we compare the results of these experiments with those arrived at by Stick, Panum, and Billroth, by using various compound vegetable and animal putrefying substances, we find the same local as well as general changes, and the conclusion bears the highest probability that in all processes of putrefaction, either an identical or very similar active principle must exist. It is satisfactorily proven that products of the termination of putrefaction, such as ammonia, sulphuretted hydrogen, are not capable of producing the above-named pathological processes. Two hypotheses only are probable: either there is during the process of putrefaction one definite chemical substance formed—one specific poison of putridity—or else, organic substances in a state of putrefaction possess the property, not yet satisfactorily explained, of transferring and communicating their own elementary or chemical condition, resembling fermentation, to other bodies. This condition consists in locomotion or separation of the elementary components.

"Neither the degree of dilution, nor the duration of putrefaction, makes any difference in the modus operandi. Comparing this fact with the first of our hypothesis, it would follow that the most different substances would create the same chemical combination, and that it would preserve its character during all stages of putrefaction, an hypothesis which is contrary to the laws of chemistry as well as to the very principle of putrefaction. We must, therefore, adhere to the doctrine which considers putrefaction as a process analagous to fermentation, according to which putrefying substances transfer their own molecular motion to substances with which they are brought in contact, causing an increased formation of cells, or the reduction of the higher and normal organic forms to pathological ones, and lower chemical compounds. Very appropriately says Helmholtz: 'Putrefaction resembles the process of life in the sameness of the substances which they both occupy, in the capability of propagation, and the identity of condition by which either is preserved or destroyed.'"

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

THE ANNUAL REPORT OF THE SURGEON-GENERAL.

THE Annual Report of the Surgeon-General for 1867 presents us with some facts of interest in connection with the mean strength, health, and death-rate of the army up to the 1st of July last, besides giving assurances of the amount of work that has been accomplished during the time specified towards completing the medical and surgical history of the late war. The average annual strength of white troops is represented at forty-one thousand one hundred and four, and that of the colored troops as six thousand five hundred and sixty-one. The constant sickness rate among the former from all causes was fifty-eight per thousand, or less than six per cent., and the mortality about four per cent.; while in the latter the sickness was rated at five per cent., and the mortality, not counting deaths from epidemic cholera, at 3.9 per cent.

As regards the medical and surgical history of the war, we are assured officially that it is actively progressing. The immensity of the work, and the amount of care which it is necessary to exercise in order to give it absolute reliability, is such as will consume much time. Reports are being rapidly accumulated from all sources, compiled, condensed, and arranged with a method that is almost perfection; and if, at the end of each succeeding year, the same good account of labors can be rendered, the progress towards completion must be rapid, sure, and satisfactory. Already we are beginning to have foretastes of what is in store, in the publication of a catalogue covering thousands of pages of imperial quarto; of a sketch of the material on hand, in the famous Circular No. 6; and lastly by the appearance of one of the most elaborate and carefully prepared reports on amputations at the hip-joint which has ever appeared in any language. This latter report, giving an account of fifty-three of these amputations, covers eighty quarto pages, and the text is sprinkled with some of the finest executed chromo-lithographs that have ever appeared in any scientific work.

We are pleased to learn that the first volume of the history is already prepared for the printer, that the following ones will be issued as soon as practicable, and that all the necessary expenses for carrying on the work as far as completed, will be covered by the appropriation last made by Congress. The profession, especially those who have been engaged in the war, should see to it that their part of the work be performed. Many of these gentlemen now out of the service are no longer under official obligations to the department; but as men of science, they owe it to themselves and humanity to complete their cases, as far as they may be able, by reports of such of the ultimate results as may have transpired within the past two or three years. A great deal has lately been done in this line by the aid of Surgeon-Generals of the different States, and by pension officers; but there are still vast numbers of interesting operations which are waiting for such results as the lapse of a year or more can alone furnish. The citizen surgeon proper should also take sufficient interest in the undertaking to furnish the results of the cases of such discharged soldiers as may consult him either in hospital or private practice. The Surgeon-General has given the profession ample reasons for believing him in earnest as regards carrying out the grand design; and they should be ready and willing not only to endorse his endeavors by commendations, but second them by the more substantial aid referred to.

WE have received from the physicians and surgeons who have attended a second private course by Prof. H. R. Storer, of Boston, some resolutions which admit of a very curious, not to say ludicrous construction. They commence thus:

"*Whereas*, An unjust prejudice, founded, partly on ignorance and professional jealousy, and partly on a false conservatism, exists in the minds of many of our profession, against those who give special attention to the diseases of women; and, *whereas*, many of these diseases are either altogether ignored, or imperfectly treated of, in our text-books, and by the teachers of medical science in our schools; and, *whereas*, Prof. H. R. Storer, in instituting and carrying out, as he has done, a plan for the more thorough instruction of physicians on these important subjects, and in taking a bold stand as a Uterine Specialist, has incurred a certain degree of misrepresentation and abuse;"

Therefore it is resolved that the pupils, eleven in all, are perfectly satisfied that their teacher does not merit any such abuse as has been heaped upon him for taking such "a bold stand" as he has; that he is everything that a specialist should be; and, besides being thankful for the "candor and impartiality" with which he has discussed the subject, they intend in future to give him their earnest and hearty support. The question naturally enough comes up as to any just cause which these gentlemen have for unanimously adopting these resolutions. In the first place, we are not aware that the professor has specially incurred the enmity of his brethren for studying uterine diseases any more than

others who have perhaps labored equally hard in that particular department. Secondly, even if the contrary were true, we hardly think that the resolutions of a few admiring pupils would have any particular weight with the profession at large, as they cannot of necessity be considered an impartial jury. The whole affair seems to be a very poor excuse on the part of the members of the said class, whose names and residences are carefully added, to advertise themselves at their teacher's expense. It is of course very gratifying to a teacher to secure the approval of his students, but we think that the latter should hardly deem it necessary to request that such an endorsement should be considered of sufficient importance to be sent to the medical press for publication.

It is to be hoped that Prof. Storer, if he has it in his power, will in future strive to curb the enthusiasm of his pupils to the extent of preventing them from begging for him the place of a martyr.

The following published letter, clipped from the *Army and Navy Journal*, New York, December 28, 1867, is commended to the careful consideration of every gentleman who contemplates entering the Medical Corps of the United States Navy:

Naval Lists.—*To the Editor of the Army and Navy Journal*,—Sir:—It is about time to notice the ridiculous way in which lists of officers of naval vessels and stations are inserted in the public prints. The New York *Herald*, of the 18th instant, has a list of officers of the *Piscataqua*, in which the line officers are ignorantly inserted after the "fleet and general staff." The impropriety of such an order of naval precedence is manifest, and cannot be defended on the ground that in lists of Army officers the field and staff have always been placed before the line. An army rule is no authority for infringing a naval custom, or else it might be urged that because army paymasters, engineers, etc., have always had rank *de facto*, in the Navy they should be styled lieutenant-commanders or majors.

Fortunately, the Navy proper is not so democratic as the Army, and they will continue to jealously guard their titles and order of precedence against the absurd pretensions of inferior branches of the service.

Honor.

The assumption of superiority claimed by the line officers under *all circumstances*, as portrayed in "Honor's" communication, exhibits a spirit of intolerance and illiberality unworthy of the age; and is a gratuitous indignity not only to the medical staff of the navy, but to the profession throughout the country.

It appears by the recent elaborate report of the Bureau of Medicine and Surgery, that there are at present about fifty vacancies in the Medical Corps of the Navy. When it is known that Congress has omitted to recognise the services of the Staff Corps by increase of rank and pay, while it has created four additional grades to reward the line, it is fair to presume the vacancies will augment rather than diminish.

Reviews and Notices of Books.

Transactions of the Medical Society of the State of Kansas, for the Year 1867.

This volume contains the proceedings of the Kansas State Medical Society, at its third annual meeting, held in Leavenworth, April 3d and 4th, 1867, with a list of members, the address of the president, C. A. Logan, M.D., of Leavenworth, and a number of papers, including reports of committees on Surgery, Obstetrics, and Climatology; on the Application of Water, and its effects as a local agent, by J. L. Prentiss, M.D.; on Diphtheria, by J. W. Brock, M.D.; on Poisoning by Arsenic, and on Persulphate of Iron as an Hæmostatic, by John W. Parsons, M.D.; Femoral Hernia, by R. Morris, M.D.; The Malarial Miasm pervading Non-malarial Diseases, by Charles C. Shoyer, M.D.; and on Infantile or Oblique Fracture of the Vertebra, by W. E. Turner, M.D.

Dr. Prentiss applies water locally, by means of a narrow tubing of light rubber of proper length, coiled in the form of a lamp mat to the desired dimensions, and retained in shape by means of light cords, one end of the tube extending from the centre of the coil and dipping into a pail of water, the other end extending from the periphery, with a stop-cock attached, to the waste-pail.

The cases of poisoning by arsenic were treated successfully by vomiting, by sulphate of zinc and the free administration of the subcarbonate of iron, which Dr. Parsons believes to be as efficient as the hydrated peroxide, mixed with water as thick as cream.

Dr. Charles C. Shoyer finds that in Leavenworth there is a periodicity complicating non-malarial diseases, and necessitating the exhibition of quinine.

We congratulate the members of the profession in Kansas upon their enterprise, and trust that they will not fail in the sphere of medical organization.

Medical Communications of the Massachusetts Medical Society. Vol. XI. No. 1. 1867.

This volume contains the proceedings of the Councillors of the Society, on October 3, 1866, February 6, 1867, and June 4, 1867. At the meeting, on the reading of a letter from S. Eliot, Esq., on the part of the Trustees of the Massachusetts General Hospital, requesting an expression of opinion as to the expediency of admitting females, as students, to visit the wards of the hospital, after a full debate it was

Resolved, That in the opinion of the Councillors of the Massachusetts Medical Society, it is inexpedient to admit females as students to our State medical schools and hospitals. 49 yeas, 7 nays.

Then follow the proceedings of the annual meeting of the Society, held at Boston, June 4, 1867, with a list of officers of the Society, and of the District Medical Societies, and a catalogue of Fellows.

Quite a number of papers on interesting subjects were read, but they are mentioned only by titles and authors. Obituaries of eight deceased members are printed in the communications. The annual address was on "The Duties of the Medical Profession," and was delivered by the orator for the year, Horace P. Wakefield, M.D., of Reading. It is a very animated address, advocating professional intercourse as a means of preventing disagreement among doctors, raising the standard of medical education, and warning the community against the errors of the day, such as the resort to criminal abortion, the use of alcoholic stimulants as beneficial in a state of health, and holding in grateful remembrance the good deeds of deceased professional associates.

On Ligation of the Funis. By A. F. A. King, M.D. Washington, D.C. 8vo., pp. 87.

This pamphlet details a number of arguments supported by clinical records, in proof of the proposition that ligation of the umbilical cord at child-birth is unnecessary, often injurious, and occasionally actually fatal to life. We shall give a good idea of the plan and scope of the argument by quoting the author's conclusions, as follows:

"1st. That ligation of the umbilical cord in the human infant is *unnecessary*. This for the following reasons:

"*a.* Because the operation is not required at the birth of any other animal.

"*b.* Because the imagined necessity for it (viz. to prevent hæmorrhage) does not exist, as distinctly appears from a knowledge of the formation of the cord, and of the structure of its component vessels; as well as from the numerous recorded cases in which no ligature was applied, and yet no fatal bleeding followed.

"*c.* Because to ligate for cleanliness' sake is superfluous.

"*d.* Because it is unreasonable to attach to the process of reproduction in women so glaring an imperfection, as that the birth of a single child cannot be safely completed without a strand of thread upon the umbilical cord.

"2d. That ligation of the umbilical cord at child-birth is in many cases *injurious*. This for the following reasons:

"*a.* Because, as shown in the text, it may justly be considered as the cause of *secondary hæmorrhage* from the umbilicus.

"*b.* Because by preventing that flow of blood which should naturally take place from the umbilical vein, and thus giving rise to congestion of the liver, it produces *infantile jaundice*, and probably also causes *sclerema*.

"*c.* Because, by interfering with desiccation of the cord, and thus preventing its separation, it gives rise to *ulceration of the navel*, and, as a not unfrequent occurrence, *erysipelas*, *fungoid excrescence*, etc.

"*d.* Because, by maintaining the funial vessels in a state of congestion and distension from unnaturally retained blood, it causes the *inflammation* of these vessels, and also hinders their normal *obliteration*, thus laying the foundation for *umbilical phlebitis*, *erysipelas*, *jaundice*, *pyæmia*, etc.

"*e.* Because, by preventing a normal escape of blood when the cord is divided, and thus causing hepatic hyperæmia and congestion of the portal circulation, it may lay the foundation for that innumerable list of fatal infantile affections which so often appear to originate in congestion of the portal blood-vessels.

"3d. That certainly in *some*, and probably in *not a few*, the operation of ligating the funis has been directly fatal. This for the following reasons:

"*a.* Because numerous cases of death, in which the fatal result was ascribed to ligation, have been recorded by the highest obstetrical authorities.

"*b.* Because, it can be seen how the operation in the cases of still-born children maintains the right ventricle in a state of distension (otherwise relieved by bleeding from the hypogastric arteries), and thus effectually prevents the renewal of the heart's action when it has stopped; or renders the stoppage complete when it is about to cease.

"*c.* Because, in many instances, the removal of the ligature has saved the life of the infant, *when all other remedies* had failed."

As to the management of the cord, our author recommends that the cord be divided with a dull pair of blunt-pointed pocket scissors, hacking through the cord, not at one cut, but by a sort of nibbling process; and he thinks a small pocket *écraseur* would be the best instrument for the purpose; if it should bleed too much—an occurrence which has not yet happened to the author—then the cut end may be scratched, scraped, and pinched between the thumb-nail and end of the index finger, until the hæmorrhage is controlled.

The author objects to dressing the cord, because it interferes with the process of desiccation, thus prolonging the period of separation; and gives pain (often mistaken by nurses for colic) by fixation of the distal end in contraction, and thus pulling the funis from the navel. In conclusion, the author claims that "the advantages of this mode of management are, that desiccation and separation take place rapidly; that pain to the child is avoided; that the risk of ulceration, inflammation, and erysipelas of the navel is lessened; and last, but by no means least, the accoucheur can in one moment, by simply raising the skirt, easily examine the umbilicus at every visit, without at all incommoding the infant, or even waking it, if asleep. This last is an advantage which every obstetrician who has witnessed the cries of the infant when undergoing examination of, and removal of dressings from the umbilicus, must, I think, appreciate."

We are unable, at present, to pass judgment upon the argument in this essay, having always adhered to the time-honored custom of ligation and dressing; but we cheerfully recommend the perusal of the pamphlet, and will leave it to obstetricians to learn if they have been taking unnecessary measures from before the days of Hippocrates. Did Eve tie Cain's funis?

The Physicians' Hand-Book for 1868. By William Elmer, M.D. New York: W. A. Townsend & Adams. 1868.

This hand-book of practice, which has met with such a favorable reception with the profession in many parts of the country, enters upon its eleventh year of existence. Its distinguishing feature, as many of our readers are aware, is the detailing of the symptoms and treatment of the various diseases met with in practice, combining the advantages possessed by an ordinary hand-book of medicine with those of a record of practice. As far as it may serve to refresh the memories of practitioners who may be called to difficult cases in an emergency, and where prompt action is required to save life, it is calculated to subserve a very good purpose. As to the general arrangement of the rest of the work, it is excellent in its way, but for our own uses we should prefer one which could be commenced at any time in the year.

Comfort for Young Anatomists.—"During my attendance at the Windmill Street school, I worked hard in the dissecting room, and learned a good deal of anatomy. If I did so, however, it must be owned that it was rather as a duty, and because it was necessary to my future undertakings, than because I had any particular taste for the details of anatomical study. I remember some years afterwards dining with a friend, who was a craniologist, at the Athenæum, when he told me that he saw that I had the organ of constructiveness much developed, and that this explained how it was that I excelled in the use of my hands, and was an excellent dissector. There was never a greater mistake. I was naturally very clumsy in the use of my hands, and it was only by taking great pains with myself that I became at all otherwise."—*Sir Benj. Brodie's Autobiography.*

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, Nov. 27, 1867.

DR. B. H. SANDS, President, in the Chair.

DR. CUTTER stated that since the last meeting he had asked Dr. Ward more particularly concerning the case of supposed gun-shot wound of the stomach, and that gentleman informed him that there had been vomiting of blood.

He then presented three photographic representations of skin disease for which he was indebted to Dr. Ward: one of these was a beautiful specimen of leprosy, and the other two were cases of elephantiasis. They were taken from subjects in Hong-Kong.

EXSECTION OF RADIUS.

He also exhibited a portion of the radius which he had exsected a week before from the arm of the daughter of a physician in Newark. The patient was of a scrofulous habit, and had been afflicted for a number of years. Three fingers of her left hand had been removed previously for necrosis, besides two or three operations upon the arm. The father stated that after these operations there had never been any effort at repair. He preferred in consequence of this to have the whole enlarged portion of the bone removed along with the sequestrum. The incision was made in the long axis of the limb, and the section made with the chain saw. The wound healed by granulation.

The specimen consisted of an expansion of bone, in the centre of which was a small splinter of necrosed bone.

DR. KRACKOWIZER asked why the opening in the involucrum had not been enlarged and the sequestrum removed.

DR. CUTTER remarked that the patient's father wished the whole removed.

DR. KRACKOWIZER believed, inasmuch as the sequestrum was entirely loose in the cavity of the involucrum that the necrotic process had ceased—the strongest possible argument in favor of enlarging the opening and removing the dead bone.

DR. CUTTER stated that he should have preferred to do so, but was overruled by the patient's father.

THE EFFECT OF ACUPRESSURE ON ARTERIES.

DR. HUTCHINSON exhibited the right and left carotid arteries of a sheep that had been cut for the purpose of ascertaining the method of closure of vessels when acupressure was employed, and the time required to effect such a result. The first vessel was cut on the 1st of November, the other on the 13th; the animal being killed yesterday, and both arteries removed.

The left carotid was the first one cut. It was exposed, and an acupressure needle used according to Simpson's fourth method. When this was applied to the artery, the vessel was cut above, and as was expected, there was hæmorrhage from the distal end. The needle was immediately applied to that side of the artery, with the effect of at once controlling the hæmorrhage. The wound was then brought together with sutures. At the end of forty-one hours, both ligatures were removed and no bleeding followed.

The same operation was done on the opposite side, as already stated, on the 13th, and the ligatures were likewise removed on the forty-first day with a like result. Dr. H. remarked that he had intended to have removed them earlier, but was prevented from so doing by being called away to the country.

"In looking at this specimen," said he, "it will be observed that there is no clot in the left carotid, either on the distal or cardiac side, that the vessel is completely closed at its mouth, and perhaps a little contracted there. On making an examination, I found the cellular tissue and sheath of the vessel connected very firmly with the extremities of the artery; the nerve was also imbedded in the mass; the vein was agglutinated, but easily separated. On the opposite side the same condition existed. It will be seen that the artery on this side was considerably larger than on the left, for the reason doubtless that the latter was first tied, and there was in consequence a greater volume of blood in the other. There are also in this vessel (right) two clots of a purplish color; one of them by accurate measurement was five-eighths of an inch, the other three-eighths of an inch in length; one of these was pyramidal at the top, the other was not. These clots were very slightly adherent to the vessel. The vessel has been laid open entirely to its mouth, which appears to be occluded by organized lymph."

He stated that the first experiment that he performed with acupressure was upon the dead subject. It was made by amputating the thigh, and afterward by introducing the nozzle of Davidson's syringe into the common iliac artery. A strong man then pumped into the vessel with sufficient force to throw a stream through the severed end of the femoral for a distance of five feet. No difficulty was found in arresting this flow by the application of the acupressure needle.

Since the experiments upon the sheep, he had performed two upon the living subject. One of these was upon a little girl whose leg was reamputated. The first operation was necessitated by the occurrence of a railroad accident, causing a compound comminuted fracture of the leg. The flaps, however, sloughed, and the bone protruded. The second operation was performed on the 7th of November by Dr. Enos, with whose permission Dr. Hutchinson employed acupressure. Four needles were applied in this case. During the amputation, the patient suffered very much from the effects of ether, and the vomiting which resulted was kept up more or less for forty-eight hours. The hæmorrhage was, however, entirely arrested by acupressure. Soon after she was put to bed, a little oozing took place after a vomiting spell, but this was only a reddish serum. The stump was accurately closed with silver sutures, but, on account of tension which soon after occurred, they were loosened forty-eight hours after the operation, when the needles were also removed. There was union by first intention throughout the whole of the wound, except about half an inch in extent.

The second operation was performed the day before the meeting, after a reamputation of the foot at the tarso-metatarsal articulation. A portion of the foot was amputated some months ago; but when the parts healed, the metatarsal bone of the little toe was found to project, and that of the fourth toe being also left, caused such a great inconvenience that the second operation had to be performed by removing the parts higher up. Five needles were used, and, in addition to these, persulphate of iron had to be applied to one of the surfaces of the bones which broke off at the articular surface. It was also necessary to apply a ligature next to the bone, and one was accordingly dipped in carbolic acid, tied, and the ends cut off short. The edges of the wound were drawn together with metallic sutures, and the acupressure needles were removed twenty-two hours after the operation. In removing the last needle, which was from the dorsalis pedis artery,

a little oozing took place, but it was only for a moment. The patient at the time of reporting the case was comfortable, and the wound looked well.

Dr. Markoe stated that in conjunction with Dr. Van Buren he had made two operations with acupressure. In both instances the needles were left in for three days, not knowing at the time that they could be taken away earlier. The wounds were large and the needle occasioned considerable stretching, followed in both cases by inflammation and suppuration. The hæmorrhage in both was promptly arrested, but in consequence of the irritation of the needles and the deformity they occasioned at the line of the flap, he had abandoned their use. These operations were made shortly after Prof. Simpson first proposed his method.

A QUESTIONABLE TUMOR OF THE JAW.

Dr. Krackowizer presented a specimen of tumor of the jaw which he had removed from a lady 35 years of age. It was situated in the region of the right parotid. About 18 or 20 years ago the patient, while still unmarried, was said to have had a similar tumor of smaller size, which the family physician who attended her, and who also assisted in this operation, removed. That gentleman said that he had good reason to believe that there had been some portion of the tumor left, for after the wound had healed the disease reappeared. The tumor, however, grew very gradually, and was never painful so long as it was small. It was lodged between the mastoid process and the ramus of the maxilla, and only by its presence occasioned an inconvenience during mastication. But when it increased so as to lift itself out of the sulcus pain began to show itself, and the annoyance of its presence was much increased. The skin overlying it was loose, and the old cicatrix was not adherent. It was removed by a longitudinal incision without any difficulty. A part of the parotid gland immediately in contact with it seemed to be atrophied by pressure.

On removal it appeared to be made up of nodules, but principally of two sets, the larger being lodged behind the ear, the other in front. These nodules seemed to be prolongations of the substance of the tumor. It was not homogeneous in structure, as some parts were hard, others soft, and some elastic.

Concerning the microscopical appearances of the tumor he begged leave to report at the next meeting. He had only thus far examined two specimens, but in these he was somewhat disappointed in what he had found. He had supposed it to be an adenoid tumor, but on microscopic inspection there was discovered a rich stroma of elastic fibres, in the interstices of which were nests of cells, the latter having small nuclei. They seemed to drop out of their places very easily, and flow in larger or smaller masses over the field of vision. But besides these, he found other nests of different sizes, which were composed of caudate or fusiform-shaped cells, which formed themselves into layers.

The aspect of the tumor, as well as its history, forbade the conclusion that it was malignant; still the microscope made some rather significant disclosures.

NECROSIS IN POPLITEAL SPACE—NECESSITY OF EARLY PROBING, ETC.

He next exhibited several pieces of dead bone which had been removed from the popliteal space of a boy 10 years of age. The patient's troubles began with the symptoms of osteo-myelitis about the middle of March. He saw him in consultation about the first week in April. One of the leading surgeons of this city had seen the patient in consultation before, and being over-conservative, had declined to open an abscess that then existed. When Dr. K. saw him the acute symptoms had passed off, and he found the knee-joint intact, the hamstring muscles shortened, the leg semiflexed on the thigh, and the lower half of the right thigh swollen, with deep fluctuation evident everywhere. An incision was made about two inches above the upper end of the patella, and a little to the inside, where fluctuation was most marked. The liquid which escaped was perfectly clear serum, except a few shreds of coagulated fibrine, and some accumulated pus globules. The finger being introduced into the opening, could be swept to the inner circumference of the thigh bone, which was denuded on its internal aspect, near and above the knee-joint.

The boy was afterward sent into the country, and returned in September. There were then two separate sinuses on the inside of the knee-joint, about two inches from each other. The probe introduced passed outward and posteriorly, and grated against dead bone. Bearing in mind the condition of things when the incision had been made, he determined, in order to get easy access to the dead bone, to make an opening between the insertions of the vastus externus and the short head of the biceps. The result was such as had been desired, and the four pieces of bone presented were removed without difficulty. The necrosis did not extend into the medullary cavity, but seemed to confine itself to the cortical portion of the bone.

He remarked that it was always of the utmost importance in such cases, after making an incision, to institute a thorough examination into the extent and situation of the denuded bone. In this case, if this had not been done, and the sinus taken as a guide for the operation, the route for the pieces of dead bone would have been much longer, and might have involved some of the large vessels in the operation.

NEW YORK MEDICO-LEGAL SOCIETY.

Stated Meeting, January 7, 1868.

Dr. Thomas C. Finnell, President, in the Chair.

APOPLEXY OF THE MEDULLA-OBLONGATA.

Dr. Terry gave the details of an autopsical examination, which he had conducted in connection with Dr. John Beach, with a view of ascertaining the cause of death in a child, five days old. The history as given by the mother was, that the child after crying almost incessantly for two days became quiet, was laid to rest at 10 P.M., and found dead at midnight. They found the abdominal and thoracic viscera healthy. The membranes of the brain were strongly congested, and in the ventricles there was a sanguineous fluid. They were then about to abandon the investigation, when it was suggested to examine the base of the brain, but without any expectation of discovering any lesion. The brain was accordingly taken out and very carefully opened. Dark coagula were found along the *medulla oblongata*, extending from the *crura cerebri* to the region of the third or fourth cervical vertebra. The clot was lying anterior, under the *dura mater* and external to the *arachnoid* membrane. He mentioned the case by way of illustrating the necessity of thorough autopsical examinations, since here both the extreme infancy and the absence of preceding symptoms scarcely suggested a suspicion as to the real lesion.

Dr. John Beach was well satisfied that such verdicts as died from "*convulsions*," "*suffocation*," "*asphyxia*," etc., were merely empirical, and expressed no scientific truth. Still, as we advanced in knowledge these verdicts would of necessity be gradually replaced by others. But we could not expect to advance the interests of our science by hasty or slovenly examinations, which

too often confirmed the habit of jumping at conclusions not at all warranted by the facts.

DR. CHADSEY recollected a child only thirteen hours old, who, after having nursed only five minutes before, suddenly died.

DR. TERRY, in reply to a question of Dr. Wooster Beach, said that the spinal cord had not been examined.

DEATH FROM EMBOLUS IN THE PULMONARY ARTERY.

DR. TERRY related a case of sudden death in a man of middle age, who had been complaining of pain in the chest, with slight difficulty of breathing, extending over a period of two weeks. The post-mortem examination revealed very slight congestion of the lungs, conjoined with a general hypostatic condition of the whole organ. The right lung, however, he noticed seemed abnormally firm and resilient, without being absolutely diseased. This condition of things induced him to look more closely into the circulatory system, when, on slitting open the pulmonary artery, he found a large embolus extending into the lungs. He would inform the Society that the cranium had been duly examined, as well as the remaining viscera, and had been found to be healthy.

DR. R. NEWMAN asked whether the embolus was the real or immediate cause of death.

DR. TERRY said that there were in the heart fibrinous clots which were externally red, but internally of a paler color. These clots were decidedly fibrinous.

DR. FINNELL said that this question, as to the real cause of death in the present case, was scarcely to be regarded as certain. Very few of us are accustomed to examine into the condition of the arteries, and, of course, a comparison of experiences could not be expected.

DR. JOHN BEACH alluded to the fact that this man had been in charge of a physician for two weeks, and was able to be about; at all events, his case did not seem to be regarded as critical.

MAY COMPRESSION OF THE BRAIN AND A CERTAIN AMOUNT OF INTELLIGENCE CO-EXIST?

DR. WOOSTER BEACH referred to the case of a man found dead in his cell. He had been brought into the station charged with being intoxicated, and when questioned by the captain of the Precinct, was able to return intelligible answers. According to the testimony elicited at the inquest, he had left his wife comparatively sober. The autopsy demonstrated the fact of a somewhat star-shaped wound of the scalp, situate just behind and above the ear, with an indentation of some depth at the junction of its several limbs. This did not lay bare the skull, although the existence of a fracture involving the petrous portion of the temporal, the parietal, and sphenoid bones was demonstrated. There was likewise found a clot so large, that it depressed the substance of the brain three-fourths of an inch. This man had been examined and sent to his cell by the police officials without there being a suspicion of any grave injury, much less does there seem to have been any attempt on their part to discriminate between intoxication and compression. A point of some medico-legal interest here comes up for consideration, Was this man "*clubbed?*" For his own part, he thought that it was probable that the deceased had fallen against the sharp corner of a stone step, as the wound from a club was usually in a straight line. Then, again, the wound was evidently quite recent, since the victim gave a coherent account of himself.

DR. O'DEA suggested that the clot might have been the result of a reactionary hæmorrhage.

DR. JOHN BEACH could hardly subscribe to the opinion that the clot had been only recently formed, and related a case in illustration of the amount of compression which might be borne by the brain, without interference with its function. The instance in question was that of a man who had walked continuously from Weehawken to Avenue A, with the exception of the time consumed in crossing the ferry, and then lived twelve hours with a similar clot on his brain. In this case the dura-mater was not injured.

DR. STIRLING suggested that the wound might possibly have been caused by a thrust with the butt-end of a club. He condemned the careless examinations of persons found in the streets, and thought that these unfortunates were entitled to the common rights of humanity. Of course, he would not say that such examinations were usual, but that they were much too frequent.

CAUSES OF SUDDEN DEATH.

DR. R. NEWMAN, in opening the discussion upon the causes of sudden death, said, that in using the term "sudden," he did not desire to be understood as meaning *instantaneous*, but that he would start with the theory that a few hours have elapsed. He then classified the causes under the following general heads:—

Internal, under which might be embraced such lesions as have been caused by the decay of parts, such as the rupture of vessels consequent upon atheromatous deposits. Familiar examples of this form are to be found in aneurisms. Besides these might be cited ruptures of the uterus, hæmorrhages within the thorax. The heart may also be cited as being frequently at fault, the lesions being rupture of its walls, and the fatty molecular degeneration of Quain. To the cranial cavity also many a death is referable; being caused by the extravasation and effusion of blood at base of the brain, etc.

External causes comprise external violence, the administration of poisons, foreign substances within trachea, suffocation by hanging and otherwise, etc.; shock to the nervous system, paralysis of an important nerve, piercing of the medulla oblongata, as practised by Bernard upon the lower animals, or in Cuba in the "garroting" of malefactors; nervous collapse after parturition, strokes of lightning, which last he supposed paralyzed the nerves by an overdose of electricity.

DR. FINNELL added another cause, the rupture of the *cordæ tendineæ*, which allowed the valve to flap back, and act as an obstruction.

DR. H. RAPHAEL also alluded to another cause, which he designated as from exhaustion, and as an instance cited the case of a patient who, having advanced to the twenty-first day after an amputation of the thigh through its middle, fell back in bed dead.

DR. O'DEA stated that the famous Dr. Pereira died suddenly, and his heart was found to have been quite flabby and soft. Dr. Abercrombie, of London, had also died from a fatty heart.

DR. WOOSTER BEACH was of opinion that this condition of fatty heart—which term he used in its accepted professional sense—was after all quite frequently a mere coincidence. He thought that when no other ostensible cause of death could be detected, medical men were too apt to betake themselves to that phrase as a refuge. He would not say that it was not a cause, but that statistics put the number of deaths from that cause at a figure much too high.

DR. FINNELL objected to Dr. Beach's view, as not being sufficiently specific.

DR. CHADSEY said that laboring men, when they did die from any cardiac disease, were apt to fall victims to ossification of the valves, while the intemperate, and

those able to live without work, died from "fatty degeneration."

Dr. Terry ventured the theory that death from lightning was due to an induced opposite electrical condition of the body, which paralyzed the nerves.

Dr. J. Beach had observed that the unacclimated furnished the greatest number of victims to sun-stroke. He had noticed, too, that in the case of those dead from either lightning or sun-stroke there was a purple hue on the countenance, and a great tendency to decomposition, which was quite rapid in progress. This condition of things he attributed to the great congestion of the whole capillary system.

The meeting then adjourned, with the understanding that the discussion be resumed at an early date.

ALBANY COUNTY MEDICAL SOCIETY.

Stated Meeting, January 18, 1867.

The President, Dr. R. H. Sabin, in the Chair.

Dr. J. S. Mosher reported a case of poisoning from *Cicuta Maculata.*

Some boys living just south of Albany were out in early spring digging and eating roots in the woods. They were taken suddenly and seriously sick, and one of them died; the others being saved probably by the prompt and efficient treatment of Dr. Wendell. A specimen of the root was brought me by him, and it proved to be the *Cicuta Maculata.* It had evidently been mistaken by the boys for the fragrant *Osmorrhiza Longistylis* (Sweet Cicely). It is one of the most poisonous plants that grow, and, unfortunately, but little known. The Shaker packages of Conium Maculatum are labelled Cicuta, and several of our best works on materia medica make no distinction between the two plants.

The Conium Maculatum, or Spotted Hemlock, is common, growing by roadsides, and is familiar to all. The genus Cicuta is represented in this country by two species, the C. Maculata, or Poison Hemlock, having two or three tuberous roots as large as the little finger, and C. Bulbifera. The C. Virosa, or Water Hemlock, is a European species, with a single large tuber, sending out a number of rootlets, and has been long known as one of the most deadly poisons. These are cerebro-spinal poisons, acting the reverse of strychnine, which has been suggested as an antidote for them. The best treatment seems to be to free the stomach by emetics, and then support with stimulants. The Order Umbelliferæ, in which these are found, also furnishes many useful plants. It is most widely known by its garden and field varieties. The caraway, carrot, parsnip, and celery, are familiar examples.

From the ignorance of the botanical character of these plants arises also ignorance of their chemical and toxicological character. There is much ground for interesting investigation in these plants. I have several of them in my garden, and intend to become better acquainted with their properties. The terrible character of the cicuta, and the complication of names which confuse it with conium, so common in medical use, are worth our serious attention.

Dr. Stevens remarked that although the Cicuta Maculata and C. Bulbifera are natives of all sections of our State, they are not very common, and hence are not generally known even by medical men. They inhabit swampy meadows and the borders of marshes, and are usually surrounded by tall grasses. Both species have marked characteristics, and if once recognized, need never afterwards be mistaken. They have finely divided leaves and white flowers; the C. Bulbifera has little bulbs in the axils of the leaves. A peculiarity of this order is that, as a rule, the plants growing in wet places contain an acrid narcotic poison, while those growing in dry places are harmless. The Cicuta Maculata and Æthusa (Fool's Parsley) are examples of the former class; the carrot, parsnip, sweet cicely, and caraway, of the latter. People should be warned to avoid all plants growing in wet places and which have umbrella-like inflorescence.

Dr. Stevens reported a case of extrophy of the bladder with an improved instrument for its relief. The bladder stood out upon the abdomen like a large tumor, raw and bleeding. The penis was a little more than an inch long, and imperforate, and the ureters opened between the bladder and penis.

Correspondence.

MEDICAL MATTERS IN PARIS.

(from our special correspondent.)

To the Editor of the Medical Record.

Sir—Before the Academy of Sciences, M. Sappey presented a note announcing the existence of nervi nervorum, or nervous filaments, in the neurilemma of nerves, analogous to the vascular ramifications in the coats of blood-vessels. The distinguished anatomist has followed these filaments as far as the sheaths enveloping the secondary trunks of nerves, but they are never found in the envelope of primitive fascicules. The internal envelope of the optic nerve receives no nervous filament. The external, on the contrary, receives a number from the ciliary nerves. This external sheath is also remarkable for the abundance of elastic fibres which enter into its composition. It therefore differs notably from both the sclerotic and the dura mater, which are deficient both in nervous filaments and elastic fibres.

THE CURVATURE OF THE SPINE AND THE OSSIFICATION OF THE RIBS.

M. Sappey is the Chef des Travaux Anatomiques, and has just reopened his popular course at the École Pratique. At a lecture at which I had the pleasure of "assisting" the other day, M. Sappey referred to two points which had been the object of some recent personal researches, and may not, therefore, be well known to you. One was an explanation of the curvatures of the vertebral column by the obliquity, in the cervical region, of the intervertebral disks, in the dorsal, of the bodies of the vertebræ, and in the lumbar, of both bodies and disks. Hirschfeld had attributed these curvatures to the action of the yellow ligament, and declared that they were destroyed by its section. M. Sappey had repeated the experiment, and found this assertion incorrect—the curvatures persisting.

The other point referred to was the ossification of the ribs. According to M. Sappey, the ribs, like the bones of the cranium and the face, pass through no cartilaginous stage, but a thread of osseous substance is found to be formed directly in the midst of the original "mucous" mass.

THE FUNCTION OF THE VASO-MOTOR NERVES.

Drs. Eulenbers and Landois have published a series of articles upon the function of the vaso-motor nerves, and upon the rôle they seem to play in a certain intermittent ophthalmia. Griesinger considers this affection to be a form of latent intermittent fever, as a neuralgia of the eye more or less severe, accom-

panied by congestion more or less intense. It is nearly always unilateral, and consists in an intense hyperæmia of the eye, with photophobia, suffusion, contraction of the pupil, and often œdema of the iris. When the disease is of long standing, it may terminate in chronic ophthalmia, or in atrophy of the bulb. Griesinger considered the presence of neuralgia essential to characterize this form of ophthalmia, but Mannhardt has reported a case where this symptom was entirely wanting.

A man thirty-six years old was suddenly attacked at nine o'clock in the morning with an acute catarrhal conjunctivitis. Intense redness and swelling of the palpebral and bulbar conjunctiva, abundant flow of tears mixed with mucous flocculi. A collyrium of acetate of lead was ordered. The next morning there was no trace of the affection, but it returned with as much intensity as ever at two o'clock in the afternoon. The same collyrium was employed, and the inflammation again disappeared, to reappear the fifth day between nine and two o'clock. Small doses of quinine were then ordered. An access of moderate intensity occurred the seventh day, but from the ninth the disease did not return.

It may therefore be admitted that the vaso-motor filaments of the trigeminus may be affected independently of the sensitive fibres, and that intermittent ophthalmia may exist uncomplicated by neuralgia.

CURIOUS PHENOMENA PRESENTED BY PRIMITIVE SYPHILITIC INDURATIONS.

In the Archives of Medicine for November, M. Fournier, a distinguished agrégé of the faculty, has called attention to certain curious phenomena occasionally presented by primitive syphilitic indurations. The first and most interesting is an ulceration of the cicatrized chancre. The second is the softening of the central and deep portions of the induration, and its progressive elimination in the form of a purulent detritus. The third phenomenon relates to the production of secondary indurations, resulting from the primitive affection, and occurring in the neighborhood of the initial chancre.

In the first case, the physician may have had to deal with a chancre which has accomplished its different phases with perfect regularity, and has cicatrized in a perfectly satisfactory and apparently definite manner. Under certain circumstances (of which an unusual abundance of the induration seems the most characteristic) this cicatrix is found to open, ulcerate, and erode in various points;—a new wound is thus formed on the surface of the induration, which sometimes excavates its entire extent. M. Fournier has observed this secondary ulceration to be repeated three times on the same base. In the cases in question the rupture of the chancre is entirely spontaneous.

Although in the greater number of cases the ulceration takes place on chancres in which the induration is excessive, it may also occur when this is of only medium intensity. The ulcer is formed from the eighth and fifteenth days after the cicatrization. Sometimes it is quite superficial, a simple erosion; sometimes it affects the excavated form. A sanguinolent rather than purulent liquid is secreted by the wound. The ulcer generally heals with remarkable rapidity, and, although sometimes alarming from its extensive and ragged aspect, it is in reality benign. Even when assuming a phagedenic form, it readily heals with only an application of dry lint.

The conversion of the cicatrized chancre into an abscess, much more rarely occurs than its ulceration. In this case, also, the cicatrix has been regularly formed, and the induration is generally excessive. Presently the centre of the mass is felt to be softened, and a little later a small opening is discovered, through which is eliminated a yellowish sanguinolent liquid, puriform rather than purulent. As many as six openings have been observed, each leading by a curiously formed little passage into a central focus of softening. The integrity of the outer layers of the mass is preserved.

It is evident that the ulcer and the abscess are really analogous lesions, each producing a liquefaction and consecutive elimination of the pathological tissue of the induration. May not the exaggeration of this latter, which has been found so generally to coincide with the lesions, be indirectly their cause, on account of opposing greater difficulty to the ordinary process of absorption?

The secondary indurations may ulcerate, and assume the aspect of primitive hard chancres. M. Fournier thinks that it is on account of cases of this kind that Babington had been led to maintain that syphilitic induration preceded ulceration. An opinion that M. Fournier has no hesitation in pronouncing erroneous, if only on account of the difficulty of diagnosis between initial chancre and herpes.

OPERATION FOR NASO-PHARYNGEAL POLYPUS.

The *Gazette des Hôpitaux* contains an account of an interesting operation practised at the Hotel Dieu of Clermont Ferrand, for a naso-pharyngeal polypus. The patient was a boy of eighteen, extremely diminutive and fragile. The polypus had apparently existed eighteen months. The right cheek was but slightly deformed, but the difficulty of speaking, and the embarrassment of the respiration, forcing the patient to keep the mouth partially open, indicated the existence of a material obstacle to the entrance of air.

The soft palate was pushed forward by a hard, resistant, bright-red tumor, whose lower border projected below the uvula, its adherent edge mounted in the pharynx. The nostril of the same side was obstructed by a fleshy mass, evidently only an expansion of the guttural tumor.

The finger, introduced between the cheek and the alveolar arcade of the upper maxilla, distinguished a small tubercle which corresponded to the exterior tumor. The point of insertion was difficult to determine; nevertheless it seemed probable that the tumor adhered rather to the pharynx than to the nasal fossa.

After some delays, during which the respiration became more and more embarrassed, M. Fleury determined to afford the patient the only chance for life that remained, by practising the resection of a portion of the maxilla, and thus extracting the tumor. The patient being under the influence of chloroform, an oblique incision was made from the commissure of the lips to the external angle of the orbit. Only one artery required ligature. The upper flap was dissected to a considerable distance, then a chain saw introduced by means of a curved needle into the spheno-maxillary cleft, to separate the maxilla from the malar bone. The second lateral incisor tooth was extracted, and the *cisailles*, introduced into the mouth and right nostril, easily divided the palatine vault—a section practised with scissors separated the apophysis of the maxilla; it then was only necessary to apply the blade of the same instrument underneath the orbit and exercise a light pressure, to loosen the bone. The soft parts uniting it to the subjacent tissues were detached with curved scissors, and the bone then easily removed. The nasal fossa and zygomatic cavity were thus laid open, and the opening, though smaller than if the maxilla had been entirely removed, was sufficiently large to give

passage to the tumor, and the risk of deformity was much less than would have been incurred by the other operation. The polypus being discovered, was much larger than had been supposed, since it occupied the cavities of the face. As much as practicable, M. Fleury endeavored to enucleate the tumor. The pedicle was implanted by a large and resistant base in the upper part of the pharynx. It was fortunately but slightly vascular, and the slight hæmorrhage following its division was easily arrested by the cautery. The tumor weighed 112 grains, and was nearly entirely fibrous.

The second day after the operation, inflammation of considerable intensity set up around the wound, and destroyed all hope of union by first intention. The following days a suspicious odor escaped from the mouth and nostrils, which was partially neutralized by lotions of chlorinated soda. The patient was extremely feeble, and a fatal termination was dreaded. However, after some days of uncertainty, the lips of the wound, which had opened, assumed a better appearance and became covered with healthy granulations, the patient was able to rise, to eat, and from that moment the convalescence was assured.

The inflammation was attributed in part to the use of the actual cautery. The wound was dressed with lint steeped in camphorated alcohol.

This is the third case in which M. Fleury has saved a patient from inevitable death, by boldly venturing on this formidable operation on the maxilla.

Among the clinics recommenced with the reopening of the year, that of M. Gosselin, who has succeeded the lamented Velpeau at La Charité, is not the least interesting. The inaugural lesson was divided into three parts. In the first the new professor paid a just tribute to the memory of his predecessor. In the second, he traced a rapid sketch of the history of this famous hospital, founded by Marie de' Medici 260 years ago. During 150 years there was no clinic, and the names of no surgeons have come down to us. The first illustrious clinician of the Charité was Desault, who instituted the *concours* for the position of assistant surgeon. Deschamps was the first who obtained this title, and also the first who availed himself in his scientific writings of observations taken among his hospital patients. Until then, observations had always been collected from the writer's private clientèle. Of all the writings of Deschamps, the best known are his "Observations on the Ligature of the Principal Arteries of the Extremities, on Account of Wounds or Aneurisms." Boyer succeeded Deschamps, and Roux followed Boyer; finally Velpeau took the place of Roux, when the latter succeeded to Dupuytren at Hotel Dieu.

The third part of the lesson was devoted to two patients in the wards, one with a fracture of the wrist, the other with an encysted encephaloid tumor at the internal and lower part of the thigh. Space does not permit me to quote at length M. Gosselin's remarks, further than that, in the latter case, he considered that amputation would not prevent a return of the tumor, but would prolong life. P. C. M.

CHLORODYNE.

To the Editor of the Medical Record.

Sir—In the late edition of Dr. Aitken's Practice of Medicine (1866), Chlorodyne is several times recommended as a valuable remedy, and a formula is given on p. 471, vol. i, which is said to be "a very useful one."

It is strange that a compound of this description should have obtained the sanction of physicians in the absence of any authentic or officinal directions for its preparation. In prescribing it, unless the nostrum is specified, the practitioner may not know which of many compounds will be furnished. I have before me five different formulas for Chlorodyne, all differing in respect to ingredients and their proportions; and not one of them would furnish a good imitation of the English nostrum.

If a chloroform-anodyne is deemed worthy of the place it now holds in public estimation, it should have a uniform composition, or be made officinal, in order to prevent the hazard and uncertainty which must now be incident to its administration. The following is Dr. Aitken's formula:

℞. Chloroform f. ʒ iv; Æth. Sulph. f. ʒ ii; Theraicæ (Treacle) f. ʒ i; Mucilag. Acaciæ f. ʒ ii; Morph. Muriat. gr. viii; Acid. Hydrocyanic. dil. (2 per cent.) ʒ ii; Ol. Menth. Pip. M. iv ad vi. *Misce bene.*

Further directions are given about combining the materials, which we have attempted to follow, but, on standing, the whole of the ether and chloroform separate from the "constituent," so that the formula cannot be considered an eligible one.

About two years ago the writer obtained a sample of Dr. Browne's genuine chlorodyne for examination. It was of a dark color, with an oder of chloroform and ether. By repeated and careful tests we failed to discover in it either cannabis or hydrocyanic acid. (The same result was obtained by Mr. Chas. Bullock in his examination of a similar article.) The "constituent" was found to be molasses, gum acacia, and ext. glycyrrhiza. It contained no peppermint. There might possibly have been a small quantity of capsicum, but the pungent effects of this and chloroform are so similar that its presence may be considered doubtful. An imitation, containing only chloroform, morphia, and ether, resembles "the genuine" in sensible properties and operative effects. I published, accordingly, the following formula for Chlorodyne, and should not have thought it of sufficient consequence to refer to it again, but for the notice taken of the compound in so respectable a work as Aitken's Practice of Medicine. The following is an imitation of Dr. J. Collis Browne's Chlorodyne.

Heat molasses in a water-bath, and remove the scum until it becomes clear. Mix one part of officinal mucilage of acacia with two parts of the molasses, to form the constituent.

Dissolve eight gr. sulphate of morphia in one drachm and a half of water, by heat, and add eight gr. powdered extract of liquorice. To this solution add one fluid drachm of conc. sulphuric ether. Add a portion of the constituent, and two fluid drachms of chloroform, and shake the mixture then add enough of the constituent to make one fluid ounce.

Ten minims, or twenty drops, contain ⅛ gr. of the morphia salt, two minims and a half or ten drops of chloroform, and half the quantity of ether

Chlorodyne thus prepared resembles the nostrum in pungency, color, density, and other properties. If the prescriber wishes to administer cannabis or hydrocyanic acid, they may be added extemporaneously.

Truly yours,

W. W. Ely, M.D.

Rochester, N. Y., December, 1867.

Loss of Memory from Syphilis.—Dr. Cerasi (*Medical Journal*, Rome, Italy), in a case of flagging intellect and loss of memory from syphilis, obtained a complete cure in two months and a half by the use of mercurial friction and iodide of potassium.

UTERINE SURGERY.

To the Editor of the Medical Record.

Sir—There is much truth and some error in the assaults now being frequently made upon the practice and teachings of modern uterine surgery. In our efforts to avoid one extreme, let us be careful that we do not fall into the other, and especially let us be careful not to be led astray by the influence of fashion in medicine. There can be no doubt that in the various operations for healing breaches of continuity in the genital organs of females, great good has been accomplished; but it is remarkable that what have within a few years been proclaimed as very valuable inventions and discoveries, should so soon have gone out of use. The clamp suture is one instance of this; and after all the later improvements, it may now well be doubted whether any that have been employed are to be preferred to that of the waxed silk, so long in use in surgical operations. Vesico-vaginal fistules were long ago cured by the use of this suture, the wound being protected from mucous secretions by the daily application of nitrate of silver and dry calomel. Cauterizations of the os and cervix, the propriety of which was long unquestioned, are now deemed worse than useless by many physicians, who have experimented with them to their hearts' content; and there are few men of experience who approve of slitting up the neck of the womb, or amputating the os, for any of the purposes recommended. The pessary has fallen into discredit, not only by its multiplied failures, but by reason of the vast variety of its forms; and some are now reverting to the ancient notion, that prolapsus is best cured by relieving the organ of its engorgements. The verdict of the profession must soon accord with that of women who have worn pessaries—hard substances cannot be worn in the vagina without inflicting injury. The use of the speculum as a means of diagnosis may sometimes be proper; but in the large majority of cases a digital examination is more satisfactory, and the speculum will be resorted to very rarely except by tyros in medicine.

Yours truly, M.

Medical Items and News.

PERSONAL.

Surgeon J. D. Miller, U.S.N., has been detached from duty as fleet surgeon of the North Atlantic squadron and placed on waiting orders.

Assistant Surgeon James N. Hyde, U.S.N., has been ordered to the Naval Hospital, Washington, *vice* Acting Passed Assistant Surgeon D. C. Burleigh detached, and ordered to the Purveyor.

Acting Assistant Surgeon Edward T. T. Marsh has been placed on waiting orders.

Dr. James Crane, of Brooklyn, has been elected President of the Health Board, *vice* Schultz, resigned.

Dr. Austin, formerly editor of the Madras *Athenæum*, and a writer in the *Saturday Review*, has been appointed special correspondent of the *Times* for the Abyssinian Expedition.

Dr. Albert Perchment, a distinguished physician of Pittsburgh, died of heart disease, Dec. 13.

Death of Surgeon Lewis Taylor.—Intelligence has been received at the Surgeon General's office of the death of Surgeon Lewis Taylor, United States Army, at Fort Wadsworth, Dakota Territory, on the 5th of January.

Medical Society, County of New York.—At the next stated meeting of the Medical Society of the County of New York (February 3d) Dr. Fordyce Barker will read a paper on "Abortion;" and Dr. O. G. Smith, on the "Paralysis of the Insane." Several members have promised to present their views on these subjects, and an interesting discussion may be expected.

Northern Dispensary.—The 41st annual meeting of the Trustees of the Northern Dispensary was held in the Board-room of that Institution, corner of Waverley Place and Christopher street, Hon. Charles T. Kirkland in the chair. The secretary's and treasurer's reports were received and adopted. These documents show that the receipts from all sources during the past year, including balance from 1866, amounted to $6,999.41, and the expenditures to $6,870.49. The total number of persons treated by the institution during the year was 21,299, of whom 12,498 were females and 8,801 males. 20,923 of these were either cured or relieved, and the balance were sent to hospital, discharged, or died. There remained under treatment, Dec. 31st, 1867, 33. A Board of Trustees for the ensuing year were then elected, and a vote of thanks offered to the chairman, and the meeting adjourned.

Bellevue Hospital.—The following are the statistics of this institution for the year just ended:—Admissions, 5,805; patients in hospital on the 1st of January, 1867, 790; total number treated during the year, 6,595; discharged from hospital, 5,264; deaths, 640; in hospital on the 1st of January, 1868, 691. The ailments of the patients were as follows:—Accidents and injuries, 1,507; obstetric cases, 626; infants born, 561; cholera, 5; all other cases, 3,106. The deaths were from the following causes:—Injuries and accidents, 147; cholera, 5; puerperal fever, 9; infants born dead, 77; Bright's disease, 113; pulmonary consumption, 146; all other causes, 143. The majority of the patients were of foreign birth; only 1,799 native-born citizens having been brought to the hospital for treatment.

Cholera at Quarantine.—The Hamburg ship Leibnitz arrived at Quarantine, Jan. 11 ult., with thirty-five cases of cholera on board, one hundred and five deaths having occurred during the voyage from the same disease.

Military Hospitals for the Abyssinian Expedition.—"Immense military hospitals," according to the *Nord* of Brussels, "are being organized at Alexandria, Cairo, and Suez; that of Suez already contains two thousand beds."

American Journal of Obstetrics and Diseases of Women and Children is to be the title of a quarterly journal shortly to be issued under the supervision of Drs. Noeggerath and Dawson, of this city. The subscription price is named at $3.00 per annum.

Average Duration of Life in Italy.—The director of the Italian Life Assurance Society, M. W. Rey, has published some interesting statistics showing the average duration of life in Italy as compared with that in other countries, from which it appears that the mortality of Italians is exceptionally great. He shows that in Italy, 22½ per cent. of the infant population die yearly, and that, even in the healthiest districts, the average duration of life is 33.43 years only, while in France it is 38.33, at Geneva, 42.02, and in England, 39.31. The number of births, too, is relatively much smaller in Italy than in England and France.

Dr. B. S. Reilley, Acting Assistant Surgeon, U. S. A., died of yellow fever at Rio Grande City, Texas, Sept. 20, 1867.

LAMENTABLE DEATH FROM CHLOROFORM.—A young lady, the wife of a lieutenant-colonel in the Confederate army, died recently at Gallatin under very painful circumstances. Being near confinement, and suffering during the night with great pain, she inhaled some chloroform on her own account. She laid the handkerchief upon her chin and fell asleep. In the morning she was found dead. This circumstance goes to prove how dangerous a plaything chloroform is.

THE KANSAS COLLEGE OF PHARMACY is the name of an association of enterprising and respectable pharmaceutists of Kansas.

MICROSCOPIC LENSES.—The improvement in lenses for the microscope began in reality with the $\frac{1}{25}$ of Powell & Leland. This glass gave an available power of from twelve to eighteen hundred diameters. The $\frac{1}{50}$ achromatic lens, with a focal distance of $\frac{1}{135}$ of an inch, of the same makers, followed. At present, there are only two of these objectives in the United States—one at the Army Medical Museum, the other the property of Dr. H. W. Atkinson, of New York City.

Much, however, is expected from a $\frac{1}{75}$ made by W. Wales, of Fort Lee, N. J., which an exchange describes as being possessed of a good definition, a flat field, and as giving two thousand diameters with ordinary light. Its focal distance is $\frac{1}{75}$ of an inch. Another peculiarity of this lens is that it can be used not only as an ordinary achromatic lens, but also as an immersion-lens; and as an "immersion" it has an extra large angle of aperture.

NUMBER OF EMIGRANTS WHO HAVE ARRIVED IN NEW YORK DURING PAST YEAR.—Two hundred and thirty-three thousand four hundred and eighteen.

BLOOD-CORPUSCLES IN CHLOROSIS.—M. Duncan, of St. Petersburgh, has just pointed out the remarkable fact that the blood-discs of chlorotic persons yield up their coloring matter more easily than do those of healthy subjects.

HEALTH BOARD STATISTICS.—The second annual report of the Metropolitan Board of Health, which has just been published, shows that during the year ending September, 1867, the number of marriages celebrated in New York City was 15,026, and in Brooklyn 1,349, and the number of births registered in New York City was 12,569, and in Brooklyn 4,878. The deaths in New York City 23,433, and in Brooklyn 8,589.

JURARE IN VERBA MAGISTRI.—There are many in this country who are wont to swear by the words of foreign masters; who, to the sound advances of home growth, yield grudgingly a half-doubting assent until they have been approved abroad; who, to the utterances of native authors, though abundantly sustained by facts, grant but a tithe of the weight they would concede to them if imported from Paris or London. We know perfectly well that the immense hospitals and extensive libraries of Europe have given our transatlantic teachers the start of us in observation, erudition, and scholasticism, and that we owe them a debt we have but just begun to repay. But we need not, on that account, forget that, for practical tact, for the power of seizing the essential truth while sifting out the unimportant, and for the shrewd interpretation of facts, the American mind is preëminent. Let us learn to appreciate and develop our originality. By the side of the literary excellence of the Philadelphia, and of the enterprise of the New York School of Medicine, we may call to mind that the wise practical counsels of James Jackson; the self-limitation in disease of Bigelow; the teachings of Ware, as, for instance, upon the different kinds of so-called croup, and the treatment of the membranous form without perturbation, and also upon the injurious effects of opium in delirium tremens; the pathological learning of John B. S. Jackson; the bold, yet careful and successful surgery of our hospitals, associated with names too prominent to need mention, recording, among other things, a method of curing vesico-vaginal fistula, quietly practised in private wards, which anticipated what has been done elsewhere; the discovery of etherization, caught up and promulgated with prompt sagacity; the brilliant and authoritative physiology of Dalton, transplanted from Boston; the treatment of syphilitic iritis without mercury, by Williams; the judicious recognition of the sway of Nature in disease, not preceded, we believe, by Forbes in his famous articles in the "British and Foreign;" all these, and much more which might be mentioned, are as valuable as though they emanated from foreign sources.

The war has emancipated public opinion and literature from subserviency to the Old World. But American physic has yet to declare its majority. We shall, of course, continue to examine what Europe has to offer us, but should see it through our own spectacles.—*Boston Medical and Surgical Journal.*

REPORT OF COMMISSIONERS OF CHARITIES AND CORRECTION.—The Commissioners of Charities and Public Correction, New York, report 90,815 persons in the Institutions during 1867. Of these, 47,646 were in the City prisons; 2,311 in the Penitentiary; 16,135 in the Workhouse; 4,033 in Almshouses; 90 in the Blind Asylum; 204 in the Hospital for Incurables; 1,535 in the Infant Hospital; 6,573 in Bellevue Hospital; 6,855 in Charity Hospital; 209 in the Small-pox Hospital; 320 in the Fever Hospital; 1,441 in the Lunatic Asylum; 153 in the Epileptic Hospital; 119 in the Paralytic Hospital; 2,040 in the Randall's Island Nurseries; 1,080 in the Randall's Island Hospitals, and 62 in the Idiot Asylum.

ESTIMATED EXPENDITURES FOR THE SUPPORT OF CHARITIES, ETC., IN THIS CITY.—Among the estimated items of expenditure for the maintenance of the government of this county for 1868, are the following: Metropolitan Board of Health Fund, $137,088; Coroners' Fees, $26,500; Asylum for Idiots, $660; Children's Aid Society, $50,000; Deaf and Dumb Asylum, $10,348; Institution for Blind, $2,760; New York Juvenile Asylum, $95,000; New York State Lunatic Asylum, $3,029; Nursery and Child's Hospital, $7,000.

ABANDONED INFANTS.—One thousand seven hundred and twenty-three infants, who had been thrown away by their parents, were picked up in the streets of this city last year, of which number 749 now fill the children's nurseries on Randall's Island.

PHTHISIS IN PERU.—On the sea-coast of Peru, as on that of the Gulf of Mexico, incipient tubercular phthisis is one of the commonest of pulmonary affections. From time immemorial, however, it has been known to the natives that a removal of phthisical patients, even in the stage of well-marked ulceration and cavities in the lungs, to the inland valley of Jauja, at a height of 10,000 feet above the sea, was followed by an almost invariable suspension of the disease—a fact which is quite corroborated by the practice of physicians at the present time. From the statistics of Dr. Fuentes, of Lima, published in 1858, it appears that nearly 80 per cent. of the cases of phthisis sent to the Jauja valley are cured. So forcibly has this fact been brought before the Peruvian Government, that it has established in this valley a military hospital for consumptive patients, and especially for native Indian soldiers, who, in the capital, are singularly prone to phthisis. Indeed, of the

whole annual mortality of Lima, no less than twenty-two and twenty-nine thirty-ninths per cent. are attributed by Dr. Fuentes to this disease. So that, as Dr. Smith remarks, we must admit that the Peruvian physicians have abundant opportunity of testing the various modes of treating it; and the unanimous opinion at which they have arrived as to its curability by a removal of the patient to the Jauja valley, leaves no doubt as to the well-founded nature of the reputation which that district enjoys. How much of this curative power may be due to the moral influence exerted by its scenery and associations, it would be difficult to say; but a nearer approach to Elysian felicity than the lives which its population are described as leading, it would be probably impossible to find in any less favored land. The harvest being home, we are told, the whole rural population rest from their agricultural labors for eight months in the year, which they give up entirely to amusements and feasting, trusting to the rain of heaven during the other four months of the year to fertilize their land and yield them more food than they require. Surely Dr. Johnson must have had this valley in his eye when he wrote his pleasing fiction of "Rasselas," for no other of which we have ever heard realizes the physical conditions under which the Prince of Abyssinia sought for the perfection of human happiness. And we may mention for the benefit of such of our readers who, as valetudinarians or philosophers, may feel an interest in knowing more about this charming region than we are able to tell them, that if the project of running regular steamers up the Amazon from Pará, 2,500 miles from its mouth, which has just been started by an American company, becomes an established fact, they will be able to transport themselves into it, almost without changing vessels, after a voyage which, though long, is not tedious nor debilitating, and which will carry them through some of the most magnificent scenery that the world can produce. —*British and Foreign Medico-Chirurgical Review.*

The New Grass which has made its appearance in the Southern States since the war, is called *Lespidosa striata*, and is said to be a native of China and Japan. It appears to be a dwarf clover, very thick set, much relished by cattle, and is a complete exterminator of Bermuda, joint, sedge, and other grasses. It was not seen before the war, and how it was introduced is a mystery among planters and botanists.—*Scien. Amer.*

Statistics of the British Army.—A correspondent of the London *Times* writes:—"Dr. Bryden's valuable tables, showing the health of the Bengal Army, English and native, and of the prisons, during 1866, have been shown to me. The death-rate of the English army was only 20.11 per 1000, while it was 32½ in the three years ending 1862, 23½ in 1863, 21 in 1864, and 24¼ in 1865. There has been a similar improvement in the rate among the women and children. In 1865 it was 42 per thousand women and 83.15 per thousand children. Last year it fell to 25½ and 76.11 respectively. The new barracks are being raised all over the country."

Mortality among Physicians at Galveston, Texas. —Not less than eight practising physicians have died of yellow fever in Houston, Texas, during the prevalence of the epidemic.

To Prevent Metals from Rusting.—Dip the article into very dilute nitric acid, and afterwards immerse it in linseed oil, allowing the superfluous portions to drain off. When the coating of oil is thoroughly dry, the article will be ready for use, and thus protected, will remain bright for years.

Discourses over the Tomb of Velpeau were pronounced in the name of the Institute by Nelaton, in the name of the Academy of Medicine by Gosselin, in the name of the Faculty by Richet, in the name of the Administration of Public Secours by Husson, in the name of the Society of Surgery by Guyson, and in the name of the friends of the deceased by Longet. Velpeau was attended most faithfully in his last illness by Nelaton and Barth.—*Gazette Hebdom.*

Proceedings against a Surgeon.—A member of the faculty, who assisted at a notorious and fatal duel which took place at Lisbon some months ago, was proceeded against, along with the other accomplices, for having attended in a case which resulted in the loss of a life. The accused, who was a military surgeon, proved that he was compelled to do the service by order of the commandant of his regiment, and that he was not there of his own free will. He was discharged. It appears to us that military discipline and the consciences of medical officers should be in accord.

Lunatic Asylums in Australia.—Two new lunatic asylums are about being established in Australia.

New Publications.

Books and Pamphlets Received.

Treatise on the Diseases of the Eye, including the Anatomy of the Organ. By Carl Stellwag von Carion, M.D., Professor of Ophthalmology in the Imperial Royal University of Vienna. Translated from the Third German Edition, and Edited by Charles E. Hackley, M.D., Surgeon to the New York Eye and Ear Infirmary, Physician to the New York Hospital, Fellow of the New York Academy of Medicine, etc.; and D. B. St. John Roosa, M.D., Clinical Professor of the Diseases of the Eye and Ear in the Medical Department of the University of the City of New York, etc. With an Appendix by the Editors. Illustrated by Ninety-six Wood Engravings and Eighteen Chromo-Lithographs. New York: William Wood & Co. 1868.

The Physician's Daily Pocket Record. Comprising Visiting List, Diary, etc., etc. By S. W. Butler, M.D. Philadelphia: Office of Medical and Surgical Reporter, 115 South Seventh Street. 1868.

Medical Society of the State of New York.

SIXTY-FIRST ANNIVERSARY.

First Day—morning session.

The Society met, pursuant to statute, in the State Geological Rooms, Albany, at 11 A.M. on Tuesday, February 4, 1868.

The President, Dr. John P. Gray, of Utica, called the meeting to order, when there being no clergyman present, the Society, on motion of Dr. March, proceeded to regular business.

ADDRESS OF THE PRESIDENT.

Dr. Gray next read his inaugural address, and in compliance with the by-law on the subject, gave a sketch of the progress of medicine during the past year. He alluded to the fact that two new medical journals had been started in the city during the time referred to, the *Medical Gazette* and the *Quarterly Journal of Psychology*, and in passing urged the members to sustain all the various medical periodicals by earnest support, both literary and pecuniary. In alluding to the subject of medical education, he deplored the low grade of requirements, and the non-existence of any law which would compel the student to study any specified time. He suggested the propriety of recommending to the legislature, not only the passage of an act naming some particular time for study, but also that the period should be four full years. The question of regulating the proper sale of drugs also came up for consideration, and some legislation was believed to be necessary to accomplish the desired object. Another point made by the speaker in his elaborate, well-timed, and able address, was the necessity of clearing away the stumbling-block to prosecutions for abortions, in the proper understanding of the term "quickening," it being desirable to make all fully amenable to the law who should destroy a fœtus that was viable.

Dr. Bissell, of Utica, offered the following, which was adopted:—

Resolved, That the President's inaugural address be referred to a committee of three, to examine and report such action thereon as may be deemed necessary on the part of the Society.

The following committees were next appointed:—

Business Committee.—Dr. E. R. Squibb, of Brooklyn; Dr. S. O. Vanderpoel, of Albany; and J. Foster Jenkins, of Yonkers.

Committee on Credentials.—Drs. Hyde, P. P. Staats, and W. H. Bailey.

Committee on Reception.—Drs. Alden March, Doolittle, and W. B. Bibbins.

Committee on President's Address.—Drs. Brinsmade, Banks, and Rochester.

The Rev. John F. Peck, at this stage of the proceedings, apologized to the Society for his absence at the time of the opening of the session, having been detained some distance from the place of meeting by the sickness of some of his parishioners.

Dr. James H. Armsby offered the following, which was carried:—

Resolved, That a committee of three be appointed to invite the physicians who are members of the Constitutional Convention and the State Legislature to participate in our deliberations during our meeting.

After which Drs. Armsby, Hall, and O. White, were appointed as said committee.

DEATH OF DRS. JOHN M'CALL AND NICHOL H. DERING.

Dr. Bissell said:—Mr. President, it is my painful duty to announce to this Society the death of two of its most worthy members since our last annual meeting, Dr. John McCall and Dr. Nichol H. Dering, both of the city of Utica.

Dr. McCall entered the medical profession in 1812 as an assistant-surgeon in the United States army, at the commencement of the war between the United States and Great Britain. Before the close of that war he was appointed a regimental surgeon, and served his country in that capacity until peace was restored in 1815, with honor to himself and the best good to the army. After an honorable discharge from the service, he commenced the practice of medicine in the county of Oneida, where he soon earned for himself an honorable standing in the profession and a lucrative practice, which he retained until stricken down by the palsy, resulting in his death. On the field of his protracted labors of more than fifty years, he was permitted to lay down his life surrounded by two generations of weeping friends. Dr. McCall, after having served for four years as a delegate from the Oneida County Medical Society, was elected a permanent member of the New York State Medical Society in 1838, just thirty years ago; therefore at the time of his death he was one of the oldest members of this body. Of those living who were present when he became a permanent member of this organization, there now remain but Elijah F. Foote, of New Haven, elected in 1827; Dr. Platt Williams, of Alder Creek, Oneida Co., elected in 1828; Dr. Edward G. Suddon, of New York, in 1831; Dr. James McNaughton, of Albany, in the same year; Dr. Joel Foster, of New York, in 1832; Dr. John P. Morgan, of St. Louis, Missouri, in 1833.

After some feeling remarks concerning the death of Dr. Dering, he offered the following preamble and resolutions, which were adopted:—

Whereas, This Society has heard with profound regret the announcement of the death of two of its most honored members since its last annual session, viz., Dr. John McCall, and Dr. Nicol Dering, both of the city of Utica; therefore,

Resolved, That in the death of our distinguished brother, Dr. John McCall, who for thirty years, as a permanent member of this Society, faithfully labored for its advancement and prosperity, and for the medical profession of our State, and who has filled with honor the highest office in the gift of the profession, we who survive him are called upon to mourn the loss of one who was ever faithful and devoted to the cause of medical science, and the improvement of the medical art, a true physician, a kind and generous friend, and a wise and judicious counsellor in all that pertained to the science and practice of medicine.

Resolved, That in the death of our deceased brother, Dr. Nichol H. Dering, of Utica, who for sixteen years was active and devoted as a permanent member of the New York State Medical Society, we are especially called on to lament the loss of one of our most cherished associates and brother members, whose long life had been devoted to the promotion of the healing art, and who had endeared himself, not only to his medical brethren, but to all who enjoyed his friendship; and in an especial manner to the poor, who at all times found him both willing and ready to minister to their wants.

Resolved, That Dr. Chas. B. Coventry, of Utica, be requested to prepare a memoir of the late Dr. John McCall, and furnish it for publication in the next volume of the Transactions of this Society.

Resolved, That Dr. M. M. Bragg, of Utica, be requested to prepare a memoir of the late Dr. Nichol H. Dering, for publication in the next volume of our Transactions.

Resolved, That the secretary furnish copies of the foregoing resolutions to the respective families of the deceased.

Prof. White, of Buffalo, made some appropriate remarks in regard to the deceased members.

APPEAL TO THE SOCIETY BY AN EXPELLED MEMBER FROM A COUNTY SOCIETY.

DR. SQUIBB, as Chairman of the Business Committee, presented an appeal from Dr. N. K. Freeman, of West Farms, Westchester Co., from a decision of expulsion from the County Society, at the same time suggesting that it would be desirable and proper to refer the matter to a Committee of Censors, who should report their decision to the Society for ultimate action.

The propriety of this measure was discussed, and culminated in the passage of the following resolution, offered by Dr. Bissell—

Resolved, That a standing committee on medical ethics, to consist of three members, be annually appointed, to whom all papers, resolutions, and other matters presented to the Society for consideration, involving questions of medical ethics, shall be referred.

Drs. Brinsmade, Hyde, and Banks, were appointed on the aforesaid committee.

DR. HUN, Chairman of the Committee on the Revision of the By-Laws, read an elaborate report, which was finally referred back, with instructions to report a complete set of by-laws at the next meeting, and have a sufficient number of the same printed for distribution at the commencement of the next annual session.

A communication was next read, inviting the members to an entertainment to be given by Drs. March and Armsby, at the City Hospital, on Wednesday evening, at 9 o'clock.

Reports were next received from the following delegates to sister societies: from Dr. H. C. Gray, as delegate to the New Hampshire State Medical Society; and from Dr. Govan, as delegate to the New Jersey State Medical Society; after which the Society adjourned, to meet at 3 P.M.

FIRST DAY—AFTERNOON SESSION.

THE Society met, pursuant to adjournment, at 3 P.M., and was called to order by the President. At the suggestion of Dr. Squibb of the Business Committee, the minutes of the meeting were to be read every morning.

The President announced the following Nominating Committee: Dr. Jos. C. Hutchison, Dr. Geo. J. Fisher, Dr. Thos. Hun, Dr. F. Burdick, Dr. D. P. Bissell, Dr. W. C. Wey, Dr. W. Manlius Smith, and Dr. C. C. Wyckoff.

The following communication was received:

STATE OF NEW YORK, IN ASSEMBLY,
ALBANY, Feb. 4, 1868.

On motion of Mr. Jacobs:

Resolved, That the Special Orders for Tuesday and Wednesday evenings of this week be set aside, that no sessions be held on those evenings; and that on Wednesday evening, the use of the Assembly Chamber be allowed to the State Medical Society.

By Order, C. W. ARMSTRONG, Clerk.

DR SQUIBB, from Business Committee, announced the reception of a report of Dr. Langworthy, Health Officer of Rochester. The secretary was directed to ask Dr. Langworthy to make an abstract for the Transactions.

LEGAL ENACTMENTS TO REGULATE PRACTICE OF DENTISTRY.

On motion, DR. WESCOTT, dentist, from Syracuse, was solicited to read a report concerning the efforts being made to obtain legislation upon the practice of dentistry. The report was received, and the following preamble and resolution, offered by Dr. Squibb, was adopted:

Whereas, The Dental profession of the State of New York (now numbering about two thousand practitioners), are about to petition the Legislature of the State for such legal enactments as will tend to regulate the practice of dental surgery, and to mark some distinction between the meritorious and skilful, and the ignorant pretender; and to give this profession a legal recognition, it is by this, the *State Medical Society*,

Resolved, That this movement on the part of the Dental profession of this State, to procure such general laws for their protection as now pertain to the Medical profession, meets with our hearty approval, and that we hereby join in the prayer of these petitioners for this purpose.

THE SULPHITE OF SODA AND GLYCERINE.

DR. JOHN H. GRISCOM, of N. Y., read a paper entitled "Therapeutic Value of Certain Articles of the Materia Medica of Recent Introduction," in which he treated more particularly of the uses of sulphite of soda as an internal, and glycerine as an external remedy. The former, by its peculiar antiseptic property, was considered by him as one of the most valuable alteratives, especially in those cases of functional dyspepsia, where it was necessary not only to arrest the fermentative process, but also to furnish an alkali. The latter substance, in consequence of its affinity for the watery elements of the blood, had, according to his observations, a marked effect in melting down all inflammatory indurations.

The paper was, on motion, referred to the Publication Committee, not however without some humorous allusions by Dr. Corliss to hobbyism in new remedies generally.

DR. MARSH introduced Prof. Barker, of New Haven, formerly of Albany. Prof. Barker gracefully responded to the introduction. Also Chas. L. Ives, of New Haven, who also addressed the Society; as did also Drs. Foster, of Portland, Maine, and Lewis A. Pendleton, of Maine.

DR. SQUIBB read by title the following papers: "Method in Medicine," presented by the Albany Co. Med. Society, by Dr. Pomfret; continuation of paper on "Monstrosity," by G. J. Fisher, of Sing Sing; all of which were referred to the Publishing Committee.

CONCERNING MONSTROSITIES AND THE N. Y. LEGISLATURE.

DR. CORLISS, at this stage of the proceedings, remarked that the subject of "Monstrosities," although interesting in its way, was hardly of such a character as to warrant its continuous publication. He was of the opinion that by incurring the expenses of the necessary woodcuts, the Society might run the risk of not having the legislature issue any volume the ensuing year.

DR. STAATS favored the same view.

DR. HUMPHREY, of the Assembly, by invitation, remarked upon the necessity of retrenching the expenses of that body by cutting down everything in the shape of papers, in the Transactions, to the smallest possible compass. He acknowledged that he loved science and progress, and endeavored to say many pretty things concerning the good that the State Society was doing, but he thought that the extra expense of a few woodcuts was too much for the impoverished legislature of New York to stand.

DR. BISSELL was inclined to differ with the honorable gentleman as to the pecuniary capability of the legislature, and thought that the Transactions of the State Society were fully as valuable as any of the large number of other documents upon which money was so lavishly spent.

DR. FISHER, the author of the essay, remarked that he had taken great pains to carry on the work properly, and in order to follow out his original design, he had gone to no little expense of time and money. Although the papers were very near completion he did not object to stopping where he was; in fact, he felt that after what had been said, it would be common

courtesy on the part of the body to invite him to proceed, if they did not choose to endorse the remarks of the members who preceded him. He also alluded to the several points which he intended to bring out, and their importance in a practical point of view.

The whole subject was decided to be out of order, and consequently no definite action upon it was taken at this time.

The Business Committee presented the following papers by title: "The Habitual Use of Alcoholic Liquors on the Public Health," by W. F. Thoms; "Effects of the Meteorological Influences on Health," by W. F. Thoms; "The Chemistry, Physiology, and Pathology of the Phosphates," by Gerardus H. Wynkoop; "Diagnosis and Treatment of Diseases of the Ear," by D. B. St. John Roosa; "Abortion," by Dr. Fordyce Barker, and "Illustrations of the Report of a Case of Removal of the Entire Scapula for Osteo Sarcoma," by Stephen Rogers. They were all referred to the Publishing Committee.

Dr. Newman read his report on "Consanguineous Marriages," and asked to have the committee continued. Report received and committee continued.

The Society then adjourned till 8 P.M.

First Day—evening session.

The Society met at 8 P.M., and was called to order by the President.

Dr. Squibb presented the "Biographical Sketch of Alden S. Sprague, M.D.," by C. C. Wyckoff; "A Report from the Madison Co. Med. Society, upon some of the Diseases of that County," by Dr. Saunders. All of which were referred to the Publishing Committee.

Dr. Garrish read his report on "Tsan-Tsi or Rhynchosa Excavata in Amenorrhœa." Referred to Publishing Committee.

Dr. Wolff moved to lay the whole subject on the table. Lost.

Dr. Garrish next presented a specimen of an acephalous monster.

Dr. Bates, from Columbia Co., made a report as delegate to the Mass. Med. Society; after which the Society adjourned until Wednesday, 9½ A.M.

Second Day—morning session.

The meeting was called to order by the President, Dr. Gray, when the Rev. Mr. Smart, of Albany, offered a prayer. The minutes of the meetings of the previous day were read and approved.

Dr. Coventry, of Utica, presented a memoir of the late Dr. John McCall, which was referred to the committee on publication.

THE USES OF THE SPHYGMOGRAPH.

Dr. S. O. Vanderpoel, of Albany, exhibited, by request, the workings of the sphygmograph. He stated that Dr. Hun, of Albany, was the first gentleman who had brought the instrument to this country, and that with him he had tested its extended applicability in a large number of cases. After stating that the instrument was destined to do for cardiac disease what the stethoscope had done for chest troubles, he described the manner in which the pulse-waves were registered, and the significance of the tracings.

Dr. March introduced Dr. Hitchcock, a delegate from the Massachusetts State Society.

Dr. Allaben, of Delaware Co., read a report of a case of compound fracture of the leg, which had occurred in that county, and for the treatment of which he had been sued in the sum of $500 for malpractice, in causing mortification, as was claimed, by tight bandaging. The facts of the case, as they appeared in the report, were adverse to such a decision. His object in presenting the case to the Society was to obtain some expression of opinion, not only upon this case, but upon similar ones. The report was referred to the Committee on Publication.

On motion of Dr. Lee, of Peekskill, the whole matter was referred to the following committee of three: Drs. Armsby, Hutchison, and Wolcott.

ANASTOMOSING ANEURISM OF THE ORBIT.

Dr. Armsby introduced the Rev. Dr. Hartwell, who, a year before, had been seized with an inflammation of the left eye, terminating in a slight protrusion of the eyeball, which had gradually been increasing until the present. The tumor was strongly pulsating in character, and could be diminished somewhat by pressure upon the carotid of that side. The diagnosis had been that of ophthalmic aneurism. The question as to an operation of ligation of the carotid came up, and would in all probability have been performed, had not an aneurismal varix suddenly made its appearance upon the prominence of the left shoulder. The patient's health was beginning to break down, and the expression of opinion on the part of the members was solicited as to the propriety of any operative interference.

Dr. March gave it as his opinion that the disease was an aneurism by anastomosis, and believed with others present that the case was a hopeless one for surgical benefit.

Dr. Quackenbush read the Treasurer's report, showing a balance of over one hundred dollars to the credit of the Society.

HOLT'S INSTRUMENT IN STRICTURE.

Dr. Hutchison, of Brooklyn, read a paper on the uses of Holt's instrument in the treatment of stricture, and cited some illustrative cases. As this paper will be presented to our readers at some future time, we shall not here make an abstract of it.

Dr. March related a case of cancer of the rectum, for which he had removed two inches of the gut. This case will also probably be published *in extenso* at a future time.

REPORT OF COMMITTEE ON PRESIDENT'S INAUGURAL.

Dr. Brinsmade, as Chairman of the committee on the President's Inaugural, offered the following, which were unanimously adopted:

The Committee to whom so much of the President's address was referred as pertains to legislative action, respectfully report:

First. That in their judgment, laws should be enacted, if possible, to secure proper qualifications and restrictions, on the part of those to whom the preparation, compounding, and sale of drugs and medicines is entrusted.

Second. That criminal abortion is of such frequent occurrence, and is so lightly regarded by the community in general, that its wickedness and enormity, and destructiveness to health, can only be made apparent by the united expression of the medical profession; and that it is the sense of the Medical Society of the State of New York, that the words, "With a quick child," in chap. 22, § 1, quoted in the address, should be stricken out, and the statute thus amended made to cover the whole period of gestation.

Third. That the remarks on the preliminary education of students, and on their proper medico-collegiate course, are most fully and thoroughly endorsed, and that all legitimate action to secure the same is most earnestly commended.

Fourth. Without further specification, the committee advise the publication and wide dissemination of the address, as presenting the sentiments of the Society and of the profession at large; and *Lastly*, They recommend the appointment of a local committee to present, if practicable, the necessary documents to the present Legislature of the State of New York, to procure such legal enactments as shall accomplish the end desired—and if that cannot be done, to present the same to the next Legislature at the commencement of its session.

THO. C. BRINSMADE,
JAMES F. BANKS,
THOS. F. ROCHESTER.

DR. CORLISS offered his report, as delegate to the Rhode Island and Vermont Medical Societies.

The following committee on the above resolutions of Dr. Brinsmade, as chairman of the Committee on President's Inaugural, was announced: Drs. Brinsmade, Banks, and Rochester.

MICROSCOPICAL EXAMINATION OF DAMAGED AND VALUABLE PAPERS.

DR. E. H. PARKER, of Poughkeepsie, remarked on the use of the microscope in detecting alterations in valuable papers. The remarks were based upon two very interesting cases of forgery, to which the doctor had been called as an expert.

The first was one in which it was an alleged promissory note, signed by a blind man who had deceased. The gentleman in question had become blind by cataract, but was nevertheless in the habit of signing all important papers. The body of this note was written by a different hand, in blue ink, and the name in black ink. The question came up as to whether the body of the said note was written before that of the signature or not.

The paper folded end to end across the middle. Prints of black ink were transferred from the black signature, and were found on the opposite side. In several places the blue and black ink of the dots were in conjunction. It was impossible to tell which was put on last, till a place was found where the bottom of a letter *y* and tip of a letter *h* came together over a dot, and showed the blue ink on top.

The same paper read, "*one day* after my death I promise to pay," etc. It showed clearly under the microscope that it had been written "one *year*," an erasure having been made and *day* written in.

The other paper was an alleged receipt for $2,000, paid on May 11th. That amount had been paid May 1st, and this alleged payment was denied to have been made. Examination by microscope showed that the first figure 1 of the date was in *brown*-black ink, while the second and the rest of the paper were in *blue*-black ink. Transfer had been made of the *brown*-black ink to the other end of the paper by folding, showing that it was put on last. The two shades of black show only under the microscope; to the naked eye they are alike.

DR. SQUIBB, in this connexion, referred to the following case: A number of U. S. bonds were stolen some time since from a party, and their payment stopped. For a long period nothing could be discovered in relation to them. Finally, however, two bonds with the same numbers were found in Wall Street, and it occurred to the parties concerned that one of these must be of the lot that had been stolen. The difficulty was to decide which was the genuine, and it was cleared up by a microscopical examination of the ruled lines upon which the figures were written in red ink. The magnifying glass showed the tracings of the old figures underneath the new, the red ink of the former having been previously removed by a chemical process.

DR. R. H. WARD, of Troy, next read a very lengthy paper with the following title: "Allopathy; an Inquiry into the relation of Sects in Medicine."

DR. CORLISS related a case of ovarian dropsy which he had tapped through the vagina.

DR. SQUIBB, in behalf of the Business Committee, stated that information had been received from Dr. Ives, of New Haven, that Elial T. Foote, a permanent member of the Society, had been a declared charlatan for many years. The said party was a resident of New Haven, and had done much, with such influence as he possessed, to damage the interests of the profession of that place.

A motion was accordingly made to drop the said name from the roll, which, after much discussion, was carried.

The Society then adjourned until 3½ P. M.

SECOND DAY—AFTERNOON SESSION.

The Society met at 3½ P.M., agreeably to adjournment. The meeting was called to order by the President.

DR. COBB moved that the Society request the Nominating Committee to present the name of Dr. Corliss for our next president. This was lost.

DR. W. WHITE made his report as delegate to the Maine Medical Society, which was referred.

DR. SQUIBB presented the report of Dr. A. N. Bell, from Committee on Hygiene. Referred.

A WORM IN THE AORTA (?).

DR. COATES, of Batavia, presented a portion of the arch of the aorta containing a lumbricoid which was discovered in that artery during a post-mortem examination of a soldier in the Ladies' Home Hospital, of New York city. The patient had died in 1864 of pneumonia, following an attack of measles. On attempting to remove the lungs by severing the vessels at their roots, the worm referred to was found alive in the cavity of the aorta. It was preserved *in situ*. The gentleman, Dr. Tozier, who forwarded the specimen, not having sent a complete history of the case, Dr. C. was unable to give any further particulars.

DR. SQUIBB pertinently remarked at this juncture, that in all probability the worm had accidentally found its way into the interior of the vessel after the death of the patient.

The Business Committee read by title a paper entitled, "Removal of Encephaloid Testicle," by Dr. Ferris Jacobs, and one on "Cæcal Inflammation and Ulceration complicated with Diseased Appendix," which were referred.

CASE OF INVERTED ACTION OF UTERUS.

DR. PETER P. STAATS, of Albany, reported a case of foot presentation which was accompanied with repeated and forcible recession of the parts. The feet were finally delivered, when a large retained placenta was found at the fundus.

DR. SQUIBB suggested that the placenta in that situation, acting as a splint, so to speak, interfered with the action of the uterine fibres, and gave a chance for those below to press the lower parts of the child upward.

DR. WM. B. BIBBINS offered the following resolution:

Resolved, That a physician of this State will not be received by this Society as an invited guest, unless he is either a member of a county medical society, or a member of the New York Academy of Medicine, or a member of the Faculty of a medical College, or a member of the Legislature.

Adopted.

DR. WHITE, of Buffalo, offered the following, which was adopted:

Whereas, Observations have been made, during an informal discussion yesterday in this Society, questioning the propriety of continuing the publication of the essay of Dr. G. J. Fisher on "Compound Monsters;" and *Whereas*, Dr. Fisher in his remarks intimated that he should "feel delicate about offering to the Society anything further on the subject."

Therefore *Resolved*, That this Society recognizes the scientific value of this essay, and earnestly requests Dr. Fisher to continue his monograph, and furnish it to the Committee of Publication.

Dr. Beadle moved the following: That the Committee on Pharmacology be directed to report to this Society the name of a member to supply the place in that Committee of Dr. Townsend, deceased. Adopted.

Dr. Squibb moved that the Society meet Thursday morning, at 9½ A.M.

On motion, the Society adjourned, to meet in the Assembly Chamber at 8 o'clock, to hear the President's Address.

The Society convened in the Assembly Chamber at 8. They were called to order by Dr. Tefft, Vice-President; after which the President, Dr. Gray, delivered his annual address.

The Annual Address.

The subject which had been chosen was the relation of the study of insanity to general medicine. After showing that insanity was properly a branch of general medical science, he gave an historical review of the progress which had been made in this study; and proved that it had been in proportion to its study as a branch of medicine rather than of mental philosophy. He stated that the ancients regarded it as a bodily disease, hence they were tolerably correct in their treatment; but during the middle ages it fell within the domain of philosophy, and was consequently misunderstood. In modern times its progress in Europe and this country had been due to the investigations of medical men taking it from the control of metaphysical speculators. He remarked that the history of the subject showed that, freed from the above-noted retarding influences, its progress had kept pace with that of general medicine, of which it was legitimately a part. Insanity was now recognized as a physical disease, and it should be taught as such in medical schools. The advantages of such teaching were then dwelt upon, after which some practical hints were offered as to how such a plan might be carried out.

The Society adjourned, to meet at 9.30 A.M. Thursday.

It was moved by Dr. Van Dyke that the thanks of this Society be tendered to Dr. Gray for his very able and interesting address. Adopted.

After the adjournment, the members assembled at the City Hospital, to respond to the invitation to an entertainment by Drs. March and Armsby. Telling addresses were made by Mr. Bogart, the Hon. Mr. Brooks, and others, after which all present partook of a bounteous and elegant supper.

Third Day—morning session.

The meeting was called to order by the President, and after a prayer by the Rev. Dr. Reese, of Albany, the minutes of the previous meeting were read and approved.

DELEGATES TO INTERNATIONAL MEDICAL CONGRESS.

Dr. Brinsmade, on behalf of the Committee of Delegates to the International Medical Congress at Paris, made the following report:—

The undersigned, delegates from this Society to the "International Medical Congress" held at Paris, on the 16th day of August, 1867, respectfully report:

That they might make sure of being duly admitted to the Congress, they called, on the 15th of August, at the office of the Secretary, M. Jaccoud, No. 4, Rue Drouot, with the certificates of their appointment by this society, and after sending up cards and waiting for some time in the ante-room, we were informed by the female concièrge that M. Jaccoud was engaged, but that we might record our names in a little book lying upon the table, and take a green "carte de membre adhérent," on which were the names of the President, M. Bouillaud, and the Secretary, M. Jaccoud, the filling up of which we were allowed to do as we might think proper.

Inasmuch as our credentials were not required, we of course reserved them for future use, if necessary. They were *never* called for, or examined by any officer or committee, showing to us that less discrimination was observed in order to give character and distinction to a scientific assembly than we were accustomed to in our own country. The card informed us of the *day* of the first séance, but neither the place nor hour of meeting was designated. After not a little inquiry we learned that the place was the great Hall of the "Faculty of Medicine." On presenting ourselves at the door, no cards or certificates were demanded, and we entered with the crowd to find seats for ourselves. The bare benches of the amphitheatre were arranged in the usual semicircular manner, without any support for the back; and gentlemen were compelled to step upon them to reach the forward seats, and in sitting were forced to use the one in front for their feet, bringing boots and coat-skirts in disagreeable proximity. The room was indeed a large one, but so imperfectly ventilated that respiration was quite difficult after remaining a few minutes. The dirty and uncomfortable seats, the heat, and the irrespirable atmosphere, prevented a majority of the audience from remaining during any entire session.

It did seem to us that in the elegant city of Paris pleasanter accommodations might have been secured wherein to receive *invited* guests, who were the accredited representatives of governments and of learned societies from all parts of the world. Your delegates deemed themselves honored by their appointment to represent so large a society from so large a State as that of New York, equalling in population and size several of the kingdoms of Europe; and confess that they felt themselves, in virtue of their office, entitled to some consideration.

But, according to French arrangements, *any* person having access to the ante-room of M. Jaccoud could avail himself of all the privileges procurable by the green ticket.

About the 6th of Jan. last your delegates received through the mail a ticket which seems to be intended as an acknowledgment—perhaps rather tardy—that they were entitled to the "Carte de membre adhérent." A large proportion of the audience seemed to be young men, perhaps young physicians, and medical students of Paris and vicinity. There were present, however, adding grace and dignity to the assembly, from cities, towns, and schools of continental Europe, many of the most distinguished medical men of the world.

Great Britain and Ireland sent but few, scarcely any, of their great surgeons and physicians. America was represented by some of our ablest men.

The names of Virchow of Berlin, Halla of Prague, De Méric of Brussels, Bérard of Montpellier, Baron Larry and Ricord of Paris, Frérichs of Berlin, Ernest Hart of London, Sangalli of Pavia, and of many others of equal celebrity, would confer honor upon any congress.

It was announced by the Secretary that on Saturday evening, Aug. 24th, a banquet would be prepared at "Le Grande Hotel" for those who would send their names, with a Napoleon, to the Secretary. About two hundred gentlemen were present at the dinner—members of the Congress, and other distinguished physicians from Paris and other cities on the Continent. The dinner was as at "Tables des Hôtes" in first-class hotels, with perhaps a few more courses, and a greater variety of fine wines. After dinner brief speeches were made by the President, M. Bouillaud, M. Palasciano of Naples, M. Teissier of Lyons, M. Jaccoud, M. Galligo of Florence, M. Piorry, M. Ricord, and Mr. Ernest Hart of London.

Your delegates received the most polite attentions from many distinguished members of the profession in Paris, and, although they feel that the result of the meeting has not been as useful to the cause of medical science as was anticipated, nor the extension of acquaintance equal to what was hoped for, yet many pleasant associations were formed, a healthful, vigorous, and generous emulation was excited, a wholesome and dignified "esprit de corps" was experienced; and I doubt not most of us, when recalling to ourselves the many pleasant and intelligent faces we have seen, the cordial greetings we have received, the evidences of ability and zeal manifested by medical brethren from various countries, will forget the uncomfortable seats, the irrespirability of the atmosphere of the Hall, and will be willing to make liberal allowance for differences in the arrangements and manner of conducting scientific associations and social reunions in different countries, and will remember with gratitude the originators and managers of the International Medical Congress, and this Society, who conferred the honor and gave us the privilege of representing it in this first attempt at an international assembly of men who do honor to their race by their benevolent efforts, and with whom all may justly feel pride in associating. The subjects of the papers which were read and discussed were some of the most important in medical science, and their character can be judged from the abstracts which have been published, and from the great ability of the authors and speakers. There was much talent exhibited, and many facts, deductions, principles, and practices were brought out which will make the first International Medical Congress long memorable.

It would be useless for your delegates to attempt anything like an analysis of the papers, as they will doubtless be published separately or together; and such ample notices of them have appeared in various medical journals, that members can obtain more correct views of their value than we shall be able to present in this report; and we simply subjoin the programme, giving the subjects in the order of their consideration, thinking it may be useful as a matter of reference.

(Signed.)

THOMAS C. BRINSMADE,
JOSEPH C. HUTCHISON,
HENRY S. DOWNS.

(Accompanying this report are the documents above referred to.)

REGISTRATION OF BIRTHS AND MARRIAGES IN THE STATE.

DR. LANSING, as chairman of the committee to present to the Legislature the subject of registration of births and marriages in this State, etc., made the following report, which was adopted:

The committee appointed at the last meeting of this Society, to present to the Legislature the subject of the registration of births, deaths, and marriages in this State, and to solicit the passage of a law providing for a thorough and efficient system of such registration, respectfully report:

That a hearing was granted your committee by the Judiciary Committee, both of the Senate and Assembly of 1866-67, and the subject duly brought before them, with such explanations and arguments on the part of your committee as seemed suitable to the occasion. The result of such interviews was an unfavorable report on the part of the committee of the Senate, who, while conceding the importance and desirability of such a law, seemed to doubt if it could be practically carried out, and to stumble at the fact of the present existing law on the subject, which remains a dead letter on the statute-book.

The committee of the Assembly noticed the subject favorably, and reported a bill substantially the same as the one contained in our last volume of Transactions, and the same was printed and placed on the files of the Assembly.

Owing to the multiplicity of other business before the Assembly, and the late period of the session at which it was brought before them, the matter failed of further progress.

The next step of your committee was to bring the subject before the governor, and a suitable memorial was prepared and submitted to him, with the expectation that he would communicate the same to the Legislature at its present session, with favorable recommendations for the passage of some such law as is desired by this Society.

It is believed that in such expectation your committee will not be disappointed.

Such is the present position of the matter in charge of your committee.

Its final success in the Legislature would seem to depend upon the merits of the measure itself, and the exertions of its friends.

Respectfully submitted,

T. F. BRINSMADE,
JOHN V. LANSING,
J. S. MOSHER,
F. B. HOUGH.

The report of the Nominating Committee was received, and on motion, it was adopted.

It was then moved to substitute the name of John P. Garrish for permanent member in the first district, for that of J. Marion Sims. Adopted.

The President, according to the action of the Society, cast a ballot in favor of the officers named by the Nominating Committee, excepting the first district, for which the Society balloted separately, with the result of the election of W. B. Bibbins and S. D. Hubbard.

OFFICERS ELECT FOR 1868.

The following is the report of the Committee of Nominations:—

For President—Dr. J. V. P. Quackenbush, Albany.
" *Vice-President*—Dr. James P. White.
" *Secretary*—William H. Bailey, of Albany.
" *Treasurer*—J. V. Lansing, of Albany.

FOR CENSORS: *Southern District.*—J. F. Jenkins, of Yonkers; Samuel H. Purdy, of New York; Edward R. Squibb, of Brooklyn. *Eastern District.*—B. P. Staats, of Albany; T. C. Brinsmade, of Troy; P. McNaughton, of Albany. *Middle District.*—M. M. Bagg, of Utica; C. B. Coventry, of Utica; A. F. Doolittle, of Herkimer. *Western District.*—Sandford Eastman, of Buffalo; Edward Hall, of Auburn; Alex. Thompson, of Aurora.

FOR COMMITTEE OF CORRESPONDENCE.—The present incumbents.

FOR PERMANENT MEMBERS: 1*st District.*—Wm. B.

Bibbins, Samuel T. Hubbard, New York. *2d District.*—Clark A. Nicholson; Lewis H. White, of Fishkill. *3d District.*—J. V. Lansing, of Albany; J. R. Boulware, of Albany. *4th District.*—John P. Shaver, of Little Falls; Isaac J. Buckbee, Fonda. *5th District.*—William Russell, of Utica; Alonzo Churchill, of Utica. *6th District.*—E. G. Crafts, Binghamton; E. Odell, Unadilla. *7th District.*—H. D. Didama, Salina; H. N. Eastman, Geneva. *8th District.*—John F. Whitbeck, of Rochester; David Little, of Rochester.

ELIGIBLE FOR PERMANENT MEMBERSHIP: *1st District.*—Edward H. Janes, of New York; George F. Shrady, New York. *3d District.*—P. V. S. Pruyn, of Kinderhook; Wm. Lamot, of Charlotteville; Jacob S. Mosher, Albany; Wm. H. Craig, Albany. *4th District.*—Francis Burdick; Henry H. Greene, of Paine's Hollow. *5th District.*—J. K. Leang; Robert Frazier, of Camden. *6th District.*—L. Griffin, Binghamton; J. W. Thompson, Schuyler Co.; J. Dolson, Bath. *7th District.* A. W. Marsh, of Palmyra; H. C. Hendricks, of McGrawville; E. J. Schoonmaker, of Magee's Corners. *8th District.*—M. W. Townsend, of Bergen; Charles E. Rider, Rochester; Julius F. Miner, of Buffalo.

FOR HONORARY MEMBERS.—N. D. Benedict, Florida; Joseph K. Barnes, Surgeon-General U. S. A.; Isaac Ray, Providence, R. I.; Thomas S. Kirkbride, of Philadelphia.

ELIGIBLE FOR ELECTION AS HONORARY MEMBERS.—Prof. Stokes, Dublin; Prof. Rawdon McNamara, Dublin; Dr. H. C. Lombard, Geneva, Switzerland; Dr. T. R. Varick, Jersey City, N. J.; Dr. Wm. Livingston, St. John's, N.B.; Sir James Y. Simpson, Edinburgh.

FOR HONORARY DEGREE OF DOCTOR OF MEDICINE.—Lewis Post, Lodi.

DELEGATES TO THE NATIONAL QUARANTINE CONVENTION.—Present incumbents.

DELEGATES TO CONNECTICUT STATE MEDICAL SOCIETY.—J. C. Hutchison, Brooklyn; Philander Stewart, Peekskill; E. S. F. Arnold, Yonkers; Arthur S. Wolff, Plattsburgh.

DELEGATES TO MASSACHUSETTS STATE MEDICAL SOCIETY.—J. F. Jenkins, Yonkers; H. D. Bulkley, New York city; G. J. Fisher, Sing Sing; Alden March, Albany.

DELEGATES TO NEW JERSEY STATE MEDICAL SOCIETY.—Ferris Jacobs, Delhi; Samuel Hart, Brooklyn; Frederic Hyde, Cortlandville; Wm. Govan, Stony Point.

DELEGATES TO NEW HAMPSHIRE MEDICAL SOCIETY.—M. R. Holbrook, of Poughkeepsie; Hiram McNutt, Warrensburgh; E. R. Peaslee, New York; W. B. Bibbins, New York.

DELEGATES TO THE VERMONT STATE MEDICAL SOCIETY.—Drs. Francis Burdick, Johnstown; J. G. Orton, Binghamton; Thompson Burton, Fultonville.

DELEGATES TO PENNSYLVANIA MEDICAL SOCIETY.—Drs. Caleb Greene, Homer; W. C. Wey, Elmira; George Burr, Binghamton; H. C. Stiles, Brooklyn.

DELEGATES TO OHIO STATE MEDICAL SOCIETY.—Drs. C. C. Wyckoff, Buffalo; Sanford Eastman, Buffalo; Thos. F. Rochester, Buffalo; H. W. Dean, Rochester; H. H. Langworthy, Rochester.

DELEGATES TO MAINE MEDICAL SOCIETY.—Drs. Ellsworth Eliot, New York; E. L. Beadle, Poughkeepsie.

DELEGATE TO RHODE ISLAND STATE MEDICAL SOCIETY. Dr. J. H. Burger, Brooklyn.

DELEGATES TO AMERICAN MEDICAL ASSOCIATION.—The present incumbents, leaving out H. A. Carrington, C. S. Wood, Seth Shore, C. M. Crandall; and adding Wm. Govan, Stony Point; Joseph Bates, J. P. White, Buffalo; H. N. Eastman, Geneva; J. F. Jenkins, Yonkers; E. S. F. Arnold, Yonkers.

COMMITTEE ON STATISTICS.—Present incumbents.

COMMITTEE ON PRIZE ESSAYS.—Present incumbents.

COMMITTEE ON PUBLICATION AND REVISION OF BY-LAWS.—Present incumbents.

DR. C. A. LEE then proposed the following resolutions in regard to an amendment of the By-Laws to be offered for consideration at the next meeting, February, 1869:

1. *Resolved*, That the by-law of the New York State Medical Society, requiring the President and Vice-President to be nominated by a committee appointed by the President, is hereby repealed.

2. *Resolved*, That, hereafter, in all elections for officers, the President and Vice-President, it shall be done by ballot by open nomination in convention, and that whoever shall receive the largest number of votes, shall be declared elected.

3. The election shall take place on the second day of the meeting, during the morning session.

After considerable discussion, the Resolutions were laid on the table, with the understanding that they be taken up and considered at the next annual meeting, the President elect also having intimated that he should call the attention of the Society to the subject, in his opening address.

DR. J. G. ORTON, through Dr. Saunders, offered the following:

Resolved, That the Standing Committee on Statistics be instructed to issue a suitable circular under the direction of the Publishing Committee, inviting reports from the profession of any epidemics which may prevail during the present year in this State. Adopted.

Dr. JOSEPH C. HUTCHISON offered the following:

Resolved, That the chairman of the delegates from this Society to the American Medical Association, be requested to present to said Association, as the desire of the Medical Society of the State of New York, the following resolution, and to urge its adoption:

Resolved, That the Faculties of the several Medical Colleges of the United States be recommended to announce explicitly in their annual commencement circulars and advertisements, that they will not receive certificates of time of study from irregular practitioners, and that they will not confer *the degree* upon any one who may acknowledge his intention to practise in accordance with any exclusive system. Adopted.

Business Committee read by title the following paper:

Report of Cholera at Quarantine, by Dr. John Swinburne, for 1867.

Moved that the Secretary be directed to advertise three times the prizes offered by this Society in the medical journals of this State. Carried.

On motion of DR. BIBBINS, a vote of thanks to the State Agricultural Society was passed, for the gratuitous use of the Agricultural Society Hall during the session of the Society. Adopted.

Business Committee read by title Carbolic Acid, by D. P. Bissell.

DR. BISSELL moved that the thanks of this Society be tendered the Committee of Arrangements, for the good accommodations and comfortable arrangements made for this Society. Adopted.

Resolved, That the thanks of the members of the Medical Society of the State of New York be tendered to Drs. Marsh and Armsby, for the kind and generous hospitality tendered to them at the Hospital Building on Wednesday evening, March 5, 1868. Adopted.

DR. BRINSMADE, on behalf of the committee appointed to memorialize the Legislature, asked that the committee be continued. Granted.

DR. SQUIBB offered the following, which was adopted:

Resolved, That the thanks of the Society are due, and hereby tendered, to the President and other officers of the present annual session.

Resolved, That the thanks of the Society are tendered to the reporters who have been present, and have reported the transactions.

Dr. C. A. Lee moved, That the thanks of this Society be given to Dr. E. R. Squibb, for the very able manner in which he has performed his duties as Chairman of the Business Committee. Carried.

DOES THE NEGRO HAVE DELIRIUM TREMENS?

Dr. B. P. Staats stated that he had considerable experience in the treatment of delirium tremens in the County Penitentiary, and had never seen one case in a negro. He asked the experience of members present.

Dr. Brinsmade, as chairman of the Committee to try the case of Dr. N. K. Freeman, reported progress, and asked that the Committee be instructed to report at the next meeting. The request after a little discussion was granted.

The Society then adjourned to the first Tuesday in February, 1869.

Progress of Medical Science.

Cubebic Acid.—The curative power of cubebs has been found to reside in cubebic acid, a crystallizable constituent, and not in the volatile oil or resins. From eight to thirty grains of this in pill, in twenty-four hours, completely cured three out of five patients in six days. In the remaining two the discharge was very much diminished, so that a few injections removed it.—*Am. Jour. Med. Sciences.*

Ossified Placenta.—Dr. Galloway, of Canton, Miss., has met, during twenty years, with eight cases. In every case the child was well developed, and the mother convalesced as usual. He makes it a rule to inspect the placenta in all cases.—*Am. Jour. Med. Sciences.*

Sub-luxation of body of sternum, producing a depression of over half an inch at the lower part of the manubrium, was reduced by Dr. M. Forster, of Shomdale, Ontario Co., as follows: He threw the head and shoulders backward, so as to draw the clavicles upward, and produced tension of the pectoral muscles, so as to draw them outward, and then by repeated deep inspirations succeeded in forcing the manubrium upward and outward.—*Am. Jour. Med. Sciences.*

Zymotic Nature of Rheumatism.—Prof. J. H. Salisbury, of Cleveland, contributes to the *Am. Jour. Med. Sciences* quite a long article upon the varieties of rheumatism and their treatment. He concludes that there are four principal types, which he names from the substance found in abnormal quantity in the blood and secretions, and excretions, either lithic, oxalic, cystinic, or phosphatic. He finds uniformly in every variety in blood and urine, and even upon the skin, a cryptogam, which he calls *Zymotoses translucens*, consisting of very minute spores and filaments, which are highly refracting, of faint outline, and which soon become nearly invisible when placed between the slides. The following directions are given: "Make an incision in the arm; a drop of blood quickly pressed out and received upon a slide should at once be covered with thin glass and watched to observe the manner in which the red discs arrange themselves, and the condition of the colorless corpuscles. Very soon little gaps will appear from the aggregation of the red discs, in which will be seen colorless corpuscles (fibrin cells) more or less aggregated, and here and there masses of minute spores, and occasionally ropes and knots of algoid filaments. As soon as the blood becomes quiet, it will be found to arrange itself to some extent in ropy rows or masses. Crystalline matters are also occasionally met with. The characteristic fungoid is also found in the urine, which, in oxalic and crystinic rheumatism, in the morning, contains the corresponding morbid excretion. The treatment of each variety is detailed at some length, but contains no especially new features.

Chloroform in Otalgia.—Dr. C. C. Shoyer, of Leavenworth, Ka., relieves earache almost immediately by introducing about half a drachm of chloroform into the meatus externus.—*Am. Jour. Med. Sciences.*

Prolonged Gestation.—Dr. P. M. Rivers, of Waterboro', S. C., relates a case in which a hydrocephalic fœtus was retained in utero until the completion of the twelfth month. The mother was troubled with abdominal pains at term, but these subsided after three days.—*Am. Jour. Med. Sciences.*

Muscle Sugar.—In August, 1861, G. Meissier announced his discovery of a true sugar in muscle. Dr. J. Rauke has reinvestigated the subject and fully confirms Meissier's supposition. The following propositions are considered as established: First. That there exists a true fermentable sugar in muscle. Second. That the amount of this sugar is increased by muscular action, including tetanization caused by strychnine or electricity. Third. That the liver has no effect in causing this increase; for the sugar is proved to arise in the muscle itself, and from the muscular substance.—*Am. Jour. Med. Sciences.*

Source of Muscular Energy.—Profs. Fick and Wislicenus give an account of an experiment which seems conclusively to show the error of Liebig's theory that muscular power is derived from the oxidation of muscle, and the truth of that advanced by Bischoff and Voit, that the oxidation of hydro-carbonaceous material is the source of that power. They ascended the Faulhorn, a peak of the Swiss Alps; during the ascent, for eighteen hours previous and six hours after it, they took hydro-carbonaceous food only, and it was found that the great muscular exertion had but very slightly increased the amount of urea excreted, and that during the six hours after the ascent even less urea was excreted than before starting. Had the source of muscular power been the oxidation of albuminous material, the urea excreted during and shortly after the ascent ought to have undergone a very decided increase. They do not deny that muscle is wasted to some extent during contraction, but they conclude that the oxidation of albuminous substances bears a very small proportion to that of hydro-carbonaceous material. Prof. Parkes has recently experimented with a view of ascertaining the correctness of these conclusions, and confirms them in the following propositions: Firstly. That on a non-nitrogenous diet of fat, starch, and sugar, exercise produces a slight but unimportant increase in the amount of nitrogen excreted both by the kidneys and the intestines. Secondly. That during the period of actual work, the amount of urea is diminished, proving that changes take place which cause either a retention of the nitrogen or an elimination by another channel. It is evident, then, that the quantity of urea excreted cannot be taken as an index of the amount of waste which the tissues have suffered. Thirdly. That amount of force expended during excretion is not merely the result of the oxidation of the muscular, nervous, and other nitrogenous tissues of the body, which can, in fact, represent only about one-fifth of the entire quantity, but that a most important share in its production is taken by the non-nitrogenous elements of the food, previous to their transformation into tissue.

Excretion of Urea.—Dr. L. R. Noyes has communicated to the *Am. Jour. Med. Sciences* the results of four weeks' experimentation, to discover the effects of food and exercise upon the excretion of urea. The subjects had for years been accustomed to an almost exclusively vegetable diet. He concludes that the urea is a measure of the metamorphosis of the tissues, rather than of surplus albuminous matters in the blood. His tables, however, seem to show that it was increased by both. All four subjects lost weight during a week of animal diet. The quantity of urine was increased twenty per cent. The sp. gr. rose from 1,020 to 10,245; the urea, however, rose 169 per cent. The total solids rose sixty-six per cent. The chlorides varied but little. The urea, then, was the substance chiefly affected by the change of diet. A vegetable regimen diminished the quantity of urine twenty-eight per cent. The sp. gr. fell from 10,245 to 1,020. The total solids diminished forty-two per cent. The urea fell seventy-five per cent. All the subjects gained in weight. He finds that during exercise the urea excreted is proportioned to the fatigue experienced. The subject who exercised most was accustomed to long walks, and suffered no fatigue. His urea was *diminished*, while the female, who took the least exercise, was most fatigued and excreted the greatest additional amount. Two cups of strong coffee were taken with each meal, instead of water, for another week. The urea increased fourteen per cent. No material change was noticed in either the quantity, the sp. gr., or the total solids. Again, the twenty-four hours were divided into two equal portions, in each of which he took one meal, both being alike, exercised, and lay upon the bed the same number of hours; the only difference being that during the day he lay awake, studying, while at night he slept. The *quantity* of urine during the day was very nearly double that during the night. The sp. gr. varied from two to five degrees, being lower during the day. The *total solids* of the day exceeded those of the night by seventy per cent. The reaction of the night urine was strongly acid, while that of the day was distinctly alkaline. The urea during the day exceeded that of the night by thirty-one per cent.

A Useful Modification of the Catheter.—Dr. T. Warden, *Lancet*, has made the following improvement in the construction of the catheter, which specially adapts itself to the wants of those patients upon whom the instrument has to be used while they are confined to their beds. From the lower side of the instrument, about three inches from the extremity, a tube is led, having about the same curve as that at the bent end. The catheter now presents the appearance of an elongated letter S, with a projecting piece at the angle of the upper curve. This part is impervious, merely serving the purpose of a handle, which may be made flattened if desired; the curved portion, which points downwards, is continuous with the tube, and has its orifice closed in the ordinary way with a wire and head. By the direction of this part, the stream can be safely directed into any kind of vessel, without the chance of wetting the patient's bed or the hands of the operator.

Granular Detritus of Elements in Process of Cadaveric Alteration.—Another very important particularity which anatomic elements present in proportion to their putrefaction, is their reduction into molecular granulations, very fine, grayish, very numerous, and gifted with very active Brownian movement. The production of these fine granulations is a phenomenon subsequent to that of the exudation of sarcodique (fleshy) drops (or gouts), and others, described above; it does not show itself until the odor of putrefying animal substances is already very manifest. The demi-solid, anatomical elements, whatever they may be, fibres or cellules, if they are homogeneous, without granulations, finally become finely granulous, in a uniform manner throughout their whole thickness. At the same time, the contour of these elements becomes pale, badly determined, and the delicate molecular granulations, floating in the liquid, become more and more abundant as these peculiarities are pronounced more decisively.—*Charles Robin in La France Médicale, Oct.* 16, 1866.

The Treatment of Infantile Diarrhœa.—Dr. Buiz (*Jour. Pract. Med. and Surg.*) expresses the following opinions, as the results of his experience, on this subject: "1. The diarrhœa of spoon-fed infants generally yields to the addition of a small quantity of bicarbonate of soda or of lime-water to the milk. 2. In summer-diarrhœa supervening without any tangible cause, from one-sixth to one-quarter of a grain of calomel three or four times a day, associated with an equal amount of ipecacuanha, will often be found efficacious. If the indisposition is consequent on exposure to cold, minute doses of opium are appropriate. 3. Chronic diarrhœa resulting from various causes may in most cases be checked with nitrate of silver, one-sixth of a grain of which may be exhibited without risk. This remedy is sometimes, however, rejected by the stomach, and should then be replaced by tonics and vegetable astringents. 4. Diarrhœa combined with anæmia and impaired nutrition, is often the result of a state of decomposition of the blood, for which the best remedy is the proto-iodide of iron. In such cases bismuth is frequently unavailing; whereas in doses of half a drachm three times a day, it is invariably successful against intestinal relaxations referable to tubercular ulceration. The causes of intestinal catarrh are, however, so obscure, that in many instances the treatment must be empirical."

Prevention of Chloroform Sickness.—It seems that the plan of administering a few drops of chloroform in water to prevent sickness, proposed by Mr. Chesshire, has been tried by Mr. J. Vose Solomon, of the Birmingham Eye Hospital, and others, and has been abandoned. He says (*British Medical Journal*): "The results of this practice, as observed by me at the Birmingham Eye Hospital, may be briefly summed up as follows: Where the patient had not been specially prepared for the inhalation, the whole contents of the stomach were rejected; where the precaution of allowing only a small breakfast of tea and toast at an early hour in the morning had been taken, some were sick, and some were exempt from that troublesome complication. There was no certainty. The prevention of sickness and retching during and after inhalation of chloroform, I find best attained, in private practice, by obliging the patient to breakfast, four or five hours before operation, upon the lean of a small, well-cooked mutton chop, four ounces of tea or coffee, and a bit of toast. In persons of highly-nervous temperament, or whose hearts are feeble, the administration of three ounces of hot brandy and water twenty minutes prior to commencement of inhalation, facilitates the action of the anæsthetic, prevents gastric disturbance, and insures satisfactory cardiac action. If the patient be kept entirely without food, or permitted to take only a cup of tea and a little toast for the early morning meal, retching of distressing urgency has been frequently observed. When the patient is much excited by the thought of the contemplated surgical procedure, the process of digestion becomes arrested, and food in a crude state is discharged by emesis.

TREATMENT OF ALBUMINOUS NEPHRITIS.—This refers simply to parenchymatous nephri is, and the treatment is only applicable to the first two stages of the complaint (congestion and exudation), and is not indicated in the third (degeneration). It consists in the administration of iodide of potassium, in large, *increasing* doses: give two or three grammes at first, then increase a gramme, every two or three days. A daily dose has thus been easily borne of from fifteen to twenty grammes. In conjunction with the iodide of potassium can be administered the iodide of iron, perchloride of iron, tannin, etc.—*M. Crocq, Medical Congress.—Gazette Hebdomadaire.*

STROKES OF THE HEART AND PULSE REPRODUCED BY PHOTOGRAPHY.—Dicrotism, that is to say, the double beat, has been described by M. Marey as a normal state of the pulse. Before the invention of the Sphymograph, it could not be determined except in certain pathological cases, as the precursor of hæmorrhages. Our photographic apparatus corroborates the assertion of my wise brother, but at the same time settles the question in a much more definitive manner. It demonstrates, indeed, that the pulse is not only *dicrotic* but even *triple* in certain cases, and that after mounting, as it were, at a single bound to the summit of the scale, it redescends by three successive falls to the inferior level. According to my observations, already numerous, the first undulation corresponds with the impulsion of the left side of the heart, the second should be due to the right side. Now the third—is it due to the elasticity of the arteries, or to the contraction of the auricles? That is a point which has not yet been demonstrated.—*M. Chas. Ozanam in Gazette Hebdom: Sept.* 6, 1867.

IDIOPATHIC BUBO AND SECONDARY SYPHILIS.—1st. BUBO, for which we can give no cause (*bubon d'emblée*), cannot be explained in the great majority of cases by the simple excitation accompanying coitus.

2d. It should be considered as making part of the array of venereal symptoms, under the same title as indurated chancre, soft chancre, blennorrhagia, balanitis, warts, etc.

3d. Facts, most scrupulously noted, will not allow us to doubt that it can, in exceptional cases, be followed by constitutional syphilitic taint.

4th. It would be desirable that statistics bearing on a great number of cases should be carefully prepared, so that the degree of frequency of unaccounted-for bubo, and the cases in which it is followed by secondary syphilis, might be established.—*Dr. Bourguet, of Aix.—Medical Congress.—Gazette Médicale de Paris, Oct.* 26, 1867.

NEW OPERATIONS ON THE EYE.—M. de Graefe took occasion to communicate three new surgical operations with their procedure.

The first has for its object the *section of the optic nerve*, in cases of remaining subjective luminous sensation, in particular affections, to the loss of the eye, and the occasion of deep troubles in the life of the patient.

The second consists in the *partial tenotomy of the elevator of the upper eyelid*, in Bandow's disease.

The third concerns the most recent modifications practised by the learned professor in his *method of linear extraction of cataract.* This modification consists in the suppression of every tractor instrument for evacuating the crystalline. Since the introduction of this modification, the number of cases of procidentia of the vitreous body has been diminished, in the proportion of from 14 in 100 to 3 in 100.—*Gazette Hebdom: Sept.* 13, 1867.

PHTHISIS AMONG THE JEWS.—While the villagers in the country where I practise are generally exempt from phthisis, the Jews are very much subject to it, so much so that the extinction of the race can be predicted in two or three generations. Bad food seems to be exclusively the cause. Meats and all substantial nourishment are forbidden fruit for them. Thin, emaciated, pale, they ever present the aspect of the "Wandering Jew." And their marriages at sixteen or eighteen years may likewise contribute to this extreme mortality. It is not climate or locality which operates in this case, but alimentation. For the most part remedies, as iodine, iron, and sulphur, act simply and only by developing the appetite. Garlic seems to be the principal nourishment of the Jews. Baths of whey (petit-lait), much employed in Austrian Gallicia, in Hungary and Bessarabia, are the most efficacious remedies.—*M. Dropsy, Medical Congress.—Gazette Hebdom: Aug.* 30, 1867.

HOLES BY BULLETS.—Bullets which penetrate in an earth half moist, like clay, make a hole larger at the entrance than at the exit. To determine this, construct a massive frame of timber and fill it in for five or six yards with clay. In firing now with a shot No. 24, the hole presents the appearance of a funnel, having a diameter of one yard and thirty centimetres at the entrance, and of fifteen centimetres at the exit. This effect is due to the transmission or not of motion, by the air. This can be proved by examining a section of either of the orifices. It is always composed of a circle with small concentric arcs, showing interruptions darkened by the sulphurous gases carried along with the bullet. In making up the total of these elements, we find exactly the length of the circumference of the projectile. The effects of communication of movement are moreover more energetic when the clay is somewhat compressed. All the resistance of the centre to the penetration is represented by two conditions—the one is dependent on the swiftness, the other is proportional to the square of this swiftness, whence we deduce the equation of the curve which is a logarithm, even as such is designated in geometry. When we turn over the profile impressions next morning we can determine a diminution in the length of all the diameters obtained, which proves that clay is gifted with a certain elasticity, which only shows itself at the end of a certain time.

The same effects have been observed on experimenting on masonry, but they are less appreciable.—*Moniteur.—From La France Médicale, October*, 1867.

ANEURISMAL TUMORS OF ARTERIES.—It seems that M. Gosselin (of late appointed as professor in the Surg. Clinic of la Charité), recently laid before the Academy of Sciences a paper on *Aneurismal Tumors of Arteries.* He has left the beaten road, and takes different ground. In this relation, *la France Médicale* says:

Contrary to the old practice, the new surgeon of *la Charité* rejects alike the ligation of the branches which nourish the tumor, or of the principal trunks of one or both of the primitive carotids, for example, when these tumors have their seat by the head, as is often the case. He has the same views, likewise, in regard to the total ablation of the tumor, which he considers as dangerous, and which indeed is only applicable in season, except where these tumors present a large surface. He prefers to all these different means, the often-repeated injection of the perchloride of iron, thrown even into the very course of the tumor. Without doubt this treatment has its inconveniences. After the injections, we may see now and then small ulcers, very exuberant and rebellious, showing themselves, by which a quantity of clots escape—these clots due to contact with the perchloride—and they retard for a long time the case. But the final result is none the less favorable.

It may happen, likewise, that phlegmasia, induced by

the perchloride, terminates in suppuration, and gives rise to consecutive hæmorrhage. In such an event, M. Gosselin employs the actual cautery, as much with a view of arresting hæmorrhage, as to complete the obliteration of the vascular tumor, and his success has decided that he was right.—*La France Médicale, Oct.* 16, 1867.

Evulsion of Arm and Scapula by Machinery.—Recovery.—Dr. Lowe, of the West Norfolk and Lynn Hospital, publishes (*Lancet*) a case of the above which is an example of an operation done accidentally, resembling that recently performed by Sir William Fergusson, and reported some time since in our columns. The patient, æt. eighteen, had his whole upper extremities drawn into the carding-machine of a flax-mill and torn to pieces. The wound was closed up immediately after the man was rescued, and the vessels were so much torn that there was very little hæmorrhage. When admitted into the hospital he was in a state of collapse. The wound having been opened, it was found that the entire upper extremity had been torn away, and the clavicle exposed over its outer half. The skin was divided almost as evenly as by a knife, and formed good anterior and posterior flaps. Over the breast and side of the face the surface was marked with lines of scratches caused by the teeth of the carding-machine. The artery and nerves, denuded to the length of four inches, were found lying in the wound, the former pulsating strongly to within a quarter of an inch of its extremity. The patient was put under the influence of chloroform, when Dr. Lowe separated the vessel and ligatured it, cutting off its exposed part as well as that of the nerve-plexus, and also removed about the outer third of the clavicle. The wound was brought together by three loose sutures, and a compress and bandage applied. The patient made a good recovery, and was in a fit condition to be discharged from the institution thirty-five days after the injury.

Several instances of a similar accident are on record. In some cases no ligature has been required. This was so in the case related by Belchier ("Philosophical Transactions," vol. xl.), and in one by James (*London Medical Gazette*, vol. v.). Other cases in which, as in Dr. Lowe's, the subclavian artery was tied, will be found described by Scarnell (*The Lancet*, 1832, p. 114), and by Cartwright (*Boston Medical and Surgical Journal*, 1837). There is also a case of Mr. Lizars' mentioned in Fergusson's "Practical Surgery," as well as reference to others described by Cheselden, Carmichael, King, and Dorsay.

The Treatment of Syphilitic Bubo.—A recent number of the *Lancet* gives a full and interesting account of the treatment of syphilitic bubo in the out-patient department of the different London Hospitals. The following may be considered the main points in said treatment: First, *rest;* second, pressure, if it will be tolerated; third, leeches; fourth, poultices, when suppuration is inevitable; fifth, a free and early incision to evacuate the contents of the abscess; sixth, a general anti-syphilitic and tonic course.

Oil and Soap of Quinine.—M. Flandrin gives the following formula for oil of quinine for external use, especially for children who refuse to take it by the mouth. Quinine, according to M. Flandrin, is soluble in about ten parts of warm and fifteen parts of cold oil. He recommends the following formula: Pure quinine, one part; oil (freed from humidity), fifteen parts. Pestle the mixture in a mortar thoroughly; pour the whole into a capsule and heat it, agitating gently till complete solution has occurred. Preserve in a dry and well-corked bottle. M. Tripier (*Journal de Médecine et de Chirurgie*), a medical officer of the army of Africa, recalls the services which soaps of the alkaloids, including quinine, have rendered him in his practice. He gives the following formula: Stearine, two parts; sulphate of quinine, one part. Warm till solution, and add a little lard to give the consistency of honey. Rub this into the armpits, groin, and plantar surfaces.

Vaccination Cicatrices and Revaccination.—Chas. E. Buckingham, on this subject, contributes the following statements to the *Boston Medical and Surgical Journal*: 1st. He has vaccinated those who have never been vaccinated before, and who never had had variola, with failure for the result. The vaccination has been repeated from the second week after birth, at various intervals, up to more than ten times, and in one case over twenty times, without success; the result sometimes being a little soreness of the skin, sometimes severe soreness, and sometimes without any apparent irritation of the skin. The matter used has been good, if the fact that a portion of the same was used successfully upon other arms be taken as evidence. 2d. He has been led to question whether the disease may not have taken the first time some of them were vaccinated, and whether they may not have vaccinia without vesicles; as many believe that patients have had scarlatina without eruptions, and measles without catarrh, and have been afterwards exposed without apparently being able to have these diseases. There is no one symptom which must exist in every case of another disease. Why not in vaccinia? 3d. He has seen virus, taken from the same arm and introduced into two others, produce in the one case the most perfect, sound, umbilicated vesicle, which, without severity, went through its regular stages; and in the other, a state of general constitutional irritation, ending in suppuration, without the first sign of vesicle. 4th. He has known two cases to terminate fatally. In one of these the virus did its work as well as in other cases. 5th. He always hesitates more about vaccinating an adult than a child, because more frequently severe symptoms follow in the adult than in the child. 6th. He has frequently advised against revaccination, because of the severe symptoms following. 7th. If not susceptible of vaccinia, the thorough introduction of its virus into one man's arm, will produce no effect; if introduced into another man's, it may act as an animal poison, and pyemia may follow. 8th. It is not improbable that the state of the patient's system may explain many of the deaths following vaccination in rebel prisons. 9th. He has seen perfectly normal-looking vesicles followed by cicatrices both large and "small, circular, marked with irradiations and indentations," and then afterward reduced to "miserable, white, flat specks," and has been unable to produce, in the possessors of these specks, anything but sore arms and headaches by revaccination. 10. The history of vaccination, for twenty years past in foreign armies, is not enough to prove the success, or necessity, or impropriety of revaccination, any more than twenty years' absence of spotted fever from Boston, or the successful result of quinine treatment of erysipelas and puerperal fever at the South Boston Almshouse, is enough to prove anything.

Gunshot Wound of the Neck, with Injury of Spinal Cord.—Private G—— was found the morning after a battle with "his neck broken." He was carried a quarter of a mile to a hospital, where he remained a few days. He was, after a few days, moved some distance, to secure better attention. After three weeks he was again moved about a quarter of a mile. The fifth day after the wound he suffered greatly, complaining of his neck and bowels; the latter being extremely pain-

ful, pulse 142, extremities cold, and excessively restless. It was found that the ball had passed through the neck, and, as well as could be ascertained, had cut across the spinal marrow. He lived fifty-one days, and finally succumbed, from dysenteric symptoms, attended with extreme and persistent nausea. Before the development of dysenteric symptoms, his bowels gave him so much pain that spasms and tetanus were thought to be imminent. Voluntary motion was almost entirely lost; he had but little use of his left hand. His evacuations were but partially under his control. On the fifty-first day he died. An examination revealed that the ball had passed through the lamina of the fourth cervical vertebra, severing entirely the lamina attached to the vertebra from the spinal portions, so that the spinal portions of the bone were lying loose in the half-formed sac around the injured bone. The sheath of the spinal marrow, posteriorly, was cut across, and about two-fifths of the spinal marrow was severed. The internal wound, including the sheath of the cord, was filled with a sanious, offensive pus, tinged with blood.—*Atlanta Medical and Surgical Journal.*

Diphtheria.—Dr. Reuben Searcy, of Alabama, thus speaks of his experience in the treatment of this disease: I now treat it with a saturated solution of chlorate of potash, acidulated with muriatic acid; *i. e.*, 100 grains of the potash, in four ounces of water, adding one drachm of muriatic acid. To a child of ten years old, give a teaspoonful every two hours, in sweetened water, and less to younger children. I directed two pieces of fat bacon to be sewed to a piece of cloth, and bound to the neck over the tonsils, and to be worn until after convalescence.* When the skin is hot and dry, rub the patient all over with a piece of bacon rind, then wash off with warm water and soap. This always lessens fever, producing sleep and perspiration. This should be repeated as often as the hot skin requires. Gentle aperients, gruels, teas, etc., should be directed, but an active purgative or emetic should never be used.—*Atlanta Medical and Surgical Journal.*

The Ligature and Mr. Syme.—Mr. Syme has bid adieu to the use of the ligature, save in the tying of the larger arteries. He employs torsion; and after this operation is completed, he clears out the wound, using a weak solution of carbolic acid and water (one part to thirty), and covers the whole over with a paste containing carbolic acid, chalk, and other ingredients.

Development and Treatment of Albuminuria.—W. F. M., a correspondent, thus writes: In view of the notorious inefficacy of our treatment of Bright's disease, I thought the following note might be interesting. It is a condensation of an article read before the French Academie Impériale de Médecine, by Prof. Semola of Naples, and is the complement of a previous memoir by the same author. In his previous communication Prof. Semola developed the opinion that the passage of the albumen into the urine, in Bright's disease, was the necessary consequence of a general deficiency of nutrition by which the albumen, rendered incapable of performing its functions, was eliminated by the kidneys as a substance foreign to the organism. According to this theory, the alterations of these organs would play only a secondary rôle in the development of the disease; and although the condition of the kidneys is of value in prognosis, Prof. Semola protests against the ideas of those who pretend to explain or resolve the question by purely anatomical deductions.

One diagnostic sign distinguishing organic from symptomatic albuminuria is furnished by the quantity of the urea, which in true Bright's disease diminishes with the first appearance of the albumen, and, at a later period, accumulates in the blood. The same is true of the sulphates. Of the artificial albuminurias, that produced by the suppression of the cutaneous functions is the most like Bright's disease. This suppression both prevents the oxidation of the materials introduced into the system in the form of peptones (the products of the digestion of albumen), and causes a congestion of the viscera, and especially of the kidneys.

Thus, according to this author, Bright's disease is not the result of a primitive anatomical lesion of the kidneys, but is a result of this double series of effects which succeed the more or less sudden suppression of the functions of the skin.

The aim of the physician should be to reëstablish these functions, and thus increase the oxidation of the peptones, and relieve the renal congestion.

Among the means best suited to this purpose are the ordinary sweatings, or, in obstinate cases, hot-air baths, always followed by cool or cold shower-baths; preparations of arsenic, and inhalations of oxygen. The diet should be vegetable or starchy, with but very little meat.

Lithotomy—the Bilateral Operation and Double Lithotome.—It is clear to my mind that first, the anatomy of the part; second, the thing to be accomplished (viz.: the extracting of the stone of large or small size, as the case may be); and third, the importance of simplifying as much as possible all surgical operations, forces the fact upon the mind of every operator that the bilateral operation is the one to make, and that the double lithotome is the instrument with which to make it.

As every operator knows, who is at all acquainted with this operation, how the perineal incisions in both methods of operating are made, it is only necessary to speak of the most important points in the operation. It is an admitted fact that the danger of cutting the internal pubic artery consists in lateralizing too much, while that of wounding the rectum is in not lateralizing enough; now this being the fact in the case, it is certainly apparent to the mind of every surgeon that as the lithotome regulates itself as to the amount of lateralization necessary, there cannot be so much danger in the hands of an operator of dividing the pubic artery as there would be by using the bistoury, and by simply depressing the handle of the lithotome and withdrawing the instrument with the back of the sheath of the blades resting in the groove of the staff or director, which should be held steadily by the assistant, closely hugging the symphysis pubis, so as to draw the neck of the bladder as far as possible from the rectum, the groove in the director being held on a line parallel with the raphe of the perineum. The question would arise in the mind of the operator, not as to how he would be enabled to avoid the pubic arteries and rectum, but rather by operating thus, how is it possible that either the pubic arteries or rectum could be injured; taking care of course not to set the blades of the lithotome too deep, keeping in view the fact that all the surgeon wants is simply a hole in the bladder large enough to admit the end of the index-finger, and relying upon dilating with finger and blade of forceps for extracting stone, in the event the size of stone should require it; and failing in this event to extract it, then always bring the lithotrite to your aid and crush it rather than risk making the opening any larger.

The inexperienced operator will be astonished to find how easily and to what extent the opening in the bladder can be dilated by the finger, or by simply expanding the blades of the forceps; and after the stone is grasped by the forceps he will be equally astonished to find how large a sized stone can by patience and manipulation be withdrawn from a very small opening.—Dr. Benjamin Franklin, *Nashville Journal of Medicine and Surgery.*

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

New York, February 15, 1868.

THE CLOSE OF OUR SECOND VOLUME.

IN closing the second volume of the MEDICAL RECORD, we take the opportunity of glancing cursorily at the medical events which have occurred during the past year. Although the record of such doings as interest medical men has not been so full as during the year before, still they are of sufficient moment to merit a retrospective glance, and to afford us an opportunity for some congratulation.

The most important event was the assembling of an International Congress at Paris. The full particulars of this meeting have been already placed before our readers, and the opinion as to its success has been, we think, fully and impartially expressed. The idea of having such a meeting at the time of the great International Exhibition was a good one, and all the leading medical minds throughout the civilized world were much interested in its success. Its failure to meet the requirements for which it was instituted was not due so much to an apathy on the part of some of the few representative men of other countries, and their indisposition to be present at its sessions, as the gross mismanagement of the affair by those of the committee who had the matter in charge. The results of the meeting, however, though they might have been, for obvious reasons, more gratifying and brilliant, were, nevertheless, good enough to warrant, under different auspices, a second undertaking of the sort. In fact the practical value of such an assemblage of scientific men was sufficiently apparent to make this congress a precursor to others, which, although not so large, were at least more successful. Among the latter we may refer to the conference at Weimar, the object of which was the discussion of the prolific subject of cholera.

The regular national medical conventions have been well attended, and the number of working members has so much increased, that a new interest has been infused into such gatherings, giving them a character with the medical public which they were far from possessing heretofore. The American Medical Association has well represented itself among other institutions of its class; and the convention of medical teachers which is its legitimate offspring, has been such a success in the harmony of its workings, as well as in the influence which it is calculated to exert upon the cause of medical education, that a similar society has been formed in Great Britain.

Of the minor societies, we are enabled to say much that is encouraging. All the State Conventions which have been in regular operation are in a most flourishing condition, and many others which have been dormant are resuscitated, while the medical men of our new States and Territories are equally active in initiating suitable measures towards following the example of those of their number in older localities. The local societies have also done equally well, and some new ones have lately been organized, which promise to do much good.

The publication of medical works has been reasonably active; numerous new editions have been issued, and not a few original treatises have made their appearance. Among the latter, without being in danger of making invidious comparisons, we may particularly mention the elaborate, elegant, and useful publication of the Catalogue of the Army Medical Museum, and the comprehensive report embodied in Circular No. 7, treating upon that important operation, amputation of the hip. Side by side with these in point of typographical excellence and superb illustrations, can rank the work on the Micro-chemistry of Poisons by Prof. T. G. Wormley, of Ohio. There are others which approach these in value of contents and neatness of form; but the ones named have such an unquestionable claim for the highest rank, that we think we have a right to allude particularly to them in the light of model publications.

Several new medical journals have made their appearance within the last twelve months, and as far as their editorial management is concerned, they seem to be, what they certainly ought to be, in a flourishing pecuniary condition. In this connection, and as an earnest of the appreciation of the labors of medical editors, we have the gratification of saying, notwithstanding the oft-repeated predictions of many, that not a single one, as far as our own knowledge goes, has ceased to be.

In the matter of progress in the medical sciences, there has been but little done in comparison with former years. Perhaps the most important advance in our knowledge which has been made refers to the views recently promulgated in regard to the inoculability of tubercle. The experiments of Villemin, Lebert, and Simon, have been of exceeding interest, and their results have furnished us with some rather startling facts. A new interest is now manifested in the study of this universally prevalent disease, which interest will in all probability be intensified when the zymotic theory, broached by Dr. William Budd, receives its promised exposition. Beyond these additions to our knowledge, there has been nothing more done, the

workers being engaged in confirming the truth or fallacy of many of those discoveries which have been brought to light within the past two or three years. It is true there are some new instruments offered us, but for the most part they are important modifications of old ones. We might refer in passing to the ingenious speculum of Bozeman as a remarkable addition to our instruments for vaginal examinations.

Death has been savagely busy with the members of our profession, and has greedily claimed more than his usual allotment of medical men. Among the honored names which live now in the past we mention those of Howard Townsend, Caspar Wistar, Benjamin Ogden, C. E. Morgan, Mason Warren, Robert Watts, and Worthington Hooker. But ours has not been the only country which has suffered in this respect. England has lost its Faraday, Brinton, Goodsir, Lawrence, Day, Warington, and Arnot; and France has been called to mourn her Jobert, Velpeau, Civiale, Trousseau, Roger, and Flourens.

With the exception of the appearance of yellow fever during the past summer, and the occasional outbreak of a few scattered cases of cholera, the people of the United States have enjoyed good health. In fact the same may be said of most of the portions of Europe. The rinderpest has practically ceased to be; the cholera did not scourge them as heretofore; and with the exception of the appearance of the epidemic fever in Ireland, nothing worthy of note in that quarter has occurred.

It is, however, useless for us to generalize further on matters which are to be found in detail in the present volume; and in closing these remarks, may we express the hope that our duties, as regards making this journal a medium of all the important discoveries in medicine, surgery, and the collateral sciences, have been satisfactorily performed. In endeavoring to do this, we have received valuable aid, not only from our numerous and talented contributors, but from the following members of our staff: Drs. John Shrady, and D. B. St. John Roosa, of New York; Dr. J. Solis Cohen, of Philadelphia; and Henry M. Lyman, of Chicago—whose readiness at all times and under all circumstances to perform onerous duties, calls from us our most heartfelt thanks. With the same staff, and with an extra determination to increase the usefulness of this journal, by making it a faithful and trustworthy chronicler of all important medical events, we enter upon the third volume.

The meeting of the State Society was an unusually large one, but we are sorry to say that its proceedings were by no means as interesting as usual. Save the addresses of the retiring President, Dr. John P. Gray, and the presentation of a very few rare cases, there was nothing to redeem the dull routine of society business. One or two of the papers read were tedious in the extreme, and we imagine that all were glad when they were finished. But such pertinacity is natural with some, and their enthusiasm leads them so far beyond the pale of propriety, that they are rather to be pitied than blamed.

Socially considered, the meeting was an immense success; and as the result of the kind efforts of our brethren in Albany, every one was made to enjoy himself. The entertainment at the City Hospital by Drs. March and Armsby was an elegant affair, and reflected great credit upon their good sense, taste, and judgment.

The result of the election was in every way satisfactory to all the members. An Association with such an influence and with such a standing as the State Society, should always exercise the greatest care in the choice of its chief officers; and it is pleasing to recollect that for year after year only representative men have occupied the posts of honor. In this respect the coming year will be as those that have passed. Dr. Quackenbush, the President elect, has for a long time occupied not only a prominent position in the profession of his city, but throughout that of the country; and now receives the well-earned, well-merited honor of the highest office in the gift of his brethren of the State. Dr. White, of Buffalo, so long and favorably known as a gynæcologist, has received the office of Vice-President, which, although second in responsibility, is not second in honor to that of the higher office. The industrious and efficient Secretary, Dr. W. H. Bailey of Albany, has been wisely retained in office. The position is the most onerous of all in the gift of the Society, and requires its holder to be specially qualified for it. Dr. Bailey has given ample evidence of his peculiar fitness for the office, and his re-election affords universal satisfaction.

Reviews and Notices of Books.

On the Pathology and Treatment of Albuminuria. By William H. Dickinson, M.D., etc. Longman, Green & Co. London, 1868. 8vo., pp. 265.

There is no branch of medicine in which greater progress has been made within the last quarter of a century than that of renal pathology; and yet, until the time of Bright, this great field of research was veiled in primeval obscurity. Since his day, Bostock, Reese, and Christison, have investigated, with marked success, the chemistry of the diseases which Bright discovered; while Wilks, George Johnson, Roger, Prout, Bence Jones, Harley, Roberts, and others, have contributed greatly by their patient and enlightened labors to elucidate the pathology and indeed the entire subject of renal affections.

The present work of Dr. Richardson must take very high rank among the numerous treatises devoted to this class of diseases; for it is an appeal to observation rather than authority, to facts rather than theory. The different chapters are devoted, 1st, to a description of the healthy kidney; 2d, to albuminous urine and fibrinous casts, in their general relation to the pathology of the kidney; 3d, the pathology of tubal nephritis, together with its clinical history, causes, and treatment; then follow, 4th, the pathology, causes, symptoms, effects, and treatment of granular degeneration; 5th, the pathology of the depurative infiltration, with its symp-

toms, clinical history, and treatment; 6th, comparison of the three forms of renal disease which are productive of albuminuria; 7th, changes of the blood in albuminuria; 8th, alcohol as a cause of renal disease; 9th, climate in relation to the same. All these subjects are graphically and beautifully illustrated by colored plates.

The description of the healthy structure of the kidney requires no special remark. The post-mortem appearances indicative of renal disease are stated to be, 1st, an alteration of the tubes by the accumulation of their contents. They may be widened, perhaps irregularly: they may contain, *first*, a great excess of epithelial growth; they may lose their epithelial lining and become bare; they may become filled with fibrinous matter. *Secondly*, the intertubular fibrous tissue may be increased, particularly near the surface of the organ; which may be detected in a microscopic section, or even by the naked eye, by observing whether or not the surface of the organ is granular. *Thirdly*, there is a peculiar material, which is recognized by the "*amyloid*" reaction with iodine, which starts from the blood-vessels and infiltrates the whole organ, giving it the appearance described as waxy. This is never found except as the result of a peculiar disease. In the classification of renal disease, the author follows an anatomical division, making three distinct varieties, viz.: 1st, disease of the secreting channels; 2d, granular degeneration, or the contracted granular kidney of Bright; 3d, the *waxy* or *amyloid* degeneration, which has its origin in the minute blood-vessels, resulting in an infiltration with a glassy material, poured out by the minute arteries, in consequence of which the organ at first assumes a whitish or anæmic look, increasing in hardness and bulk, till at length it presents a translucent or "waxy" aspect. The grand characteristic of the change is in the action of iodine, which imparts to the new deposit a dark brown color, unlike the yellow tint which the healthy parts of the gland receive from the same reagent; and which change does not take place in any other form of renal disease.

The presence of *albumen and casts* in the urine is traced to, 1st, congestion; 2d, a specific change in the arteries, which renders their walls unnaturally pervious; and 3d, a loss by the secreting tubes of their epithelial lining. We pass over the "pathology" and "clinical history" of "tubal nephritis," to speak of the treatment. The author condemns the practice of general bleeding in this disease, as recommended by Bright and Christison, though he thinks moderate cupping from the loins may sometimes do good, but especially dry cupping. He condemns purging and hot-vapor baths, but speaks favorably of the very free use of pure water and the infusion of digitalis, for the purpose of increasing the amount of urine. After the acute stage is passed, he advises the use of perchloride of iron, followed by acetate of potash. He also speaks favorably of combining this last-named remedy with acetate of iron, or bitartrate of potash with wine of iron; also the citrate of iron and quinine. The more stimulating diuretics, as nitre, juniper, and squills, are to be resorted to if the disease assumes a chronic form. If the dropsy be so severe as to call for mechanical relief, the author advises puncturing with needles instead of the lancet, as less likely to cause erysipelatous inflammation. For the treatment of head symptoms, he recommends small doses of opium, chloroform, active aperients, and diuretics, with the exception of cantharides. He cautions against the use of mercurials, even in small doses. Inflammatory complications are to be treated in such a manner as not to interfere with the management of the primary disease.

The morbid anatomy of *granular degeneration* of the kidney is well described and beautifully illustrated by the colored plates. The different stages of the disease are accurately traced in connection with the causes and symptoms; and especially its complications with heart-disease, pregnancy, blindness, gout, and lead-poisoning, atheroma, etc. Among the accidents of the disease, inflammatory attacks, hæmorrhagic attacks, uræmic poisoning, etc., are particularly discussed. The chemical and other changes in the urine are also pointed out. Every form of the disease is well illustrated by cases. The principal points of treatment in this disease are attention to the secretions of the skin, which must be kept active; the patient should be clothed in flannel, and take much active exercise; resort at regular intervals, say twice a week, to the hot-air or Turkish bath, or the vapor bath, which are most useful where the urine is copious. Besides these measures, it will generally be necessary to give *iron:* the citrate or acetate answers the purpose; with which the acetate of ammonia or acetate of potash may be combined. If the urine contain blood, the sulphate or perchloride of iron may be used. The food should be as non-nitrogenous as is consistent with the proper nutrition of the patient. An entire abstinence from animal food is not recommended. No harm has been observed to follow the moderate use of alcoholic liquors, as gin or wine. Beer is to be forbidden to gouty subjects. The dropsy is to be treated by diuretics, mixed and varied until a suitable one is found. Christison recommends a combination of squills, digitalis, and bitartrate of potassa. The author thinks one of the best is a decoction of scoparium taken freely. If œdema resists the action of such remedies, then the practitioner must resort to purgatives and diaphoretics; as the compound jalap powder twice a week, and occasional vapor baths. For the treatment of stomach symptoms, nitric and hydrochloric acids and strychnia are recommended, given with colombo, or some other mild bitter. Acids are often useful. For vomiting and gastric disturbances, hydrocyanic acid, creasote, brandy, and soda-water, ice, etc., are advised as worthy of trial.

There are some important statistical statements scattered throughout the work, from which we gather the following: Of thirty-nine fatal cases of tubal nephritis, eighteen had hæmaturia; thirty-eight œdema; twenty ascites; eleven hydrothorax; ten uræmic convulsions; ten pneumonia; nine vomiting; eight bronchitis, etc. As to duration of the disease, the younger the patient, the more rapid the course to recovery or death. During childhood the majority of fatal cases terminate during the first month, many within the first week. Few survive the third month, none the fifth. After the age of twenty, no deaths took place within a week, few within the first two months. The greater number of cases terminate after the end of the second month, before that of the sixth.

In forty fatal cases under sixteen, pneumonia was the cause of death in fifteen; pleurisy in ten; uræmic convulsions in five; hydrothorax in three; peritonitis in three; and vomiting in three. Of the age of sixteen and upward, coma or convulsions was the cause of death in five; inflammation of the respiratory organs in two; dropsy in four; peritonitis in two. The urine was greatly diminished in quantity in all. Granular degeneration is almost unknown before the age of twenty. It is most common about the age of fifty. Of 153 cases of fatal valvular disease of the heart, twenty-nine had the kidneys hard, congested, enlarged, but still smooth. In sixty-seven the kidneys had granular surfaces, and more or less contracted cortices. Dr. Barclay also found twenty-eight cases of granular kidneys in seventy-nine cases of valvular disease (Med. Chir. Trans. v. 31, p. 196);

no other form of renal disease has any dependence upon changes in the valves. The disease in a great majority of cases commences in the heart. In reference to pregnancy as a cause of renal disease, in consequence of pressure on the renal veins and vena cava, to which attention was first called by Sir J. Simpson, different writers give different results in regard to the presence of albumen in the urine. Litzman found it present in thirty-seven out of 131 pregnant or lately delivered females; of which twenty-six were primiparæ. Dr. Blot detected albumen in the urine of forty-one out of 205 pregnant women; most of them cases of first pregnancy. It is well known that pregnancy often occasions enough renal congestion to render the urine albuminous; causing various constitutional symptoms, as œdema, disorders of vision, convulsions, headache, etc. But in a vast majority of cases after delivery, the kidneys return to their normal condition. In sixty-nine fatal cases of granular degeneration, sixteen were dependent on or coincident with gout; thirty per cent. of cases are dependent on lead-poisoning. Of forty-two fatal cases in men, treated by the author, twenty-six had distinct granular degeneration of the kidneys; alcohol affects the joints, lead the kidneys. In 250 cases of the disease, the liver was cirrhosed in thirty-seven. In forty-eight per cent. there is cardiac enlargement; in fifty-two per cent. there is atheroma. Hæmorrhagic attacks are often consequent on this disease. Of seventy-five victims of apoplexy examined at St. George's Hospital, thirty-one were found to have had granular degeneration of the kidneys. In another series of cases, Dr. Jones (*British Med. Jour.* 1862) found in thirty-six fatal cases of apoplexy, twenty-nine in which the kidneys were extensively diseased. In twenty-four the organs were small, hard, granular, with thin cortical substances diminished; so that of fatal attacks of apoplexy, one-half at least are preceded by granular degeneration of the kidney. The renal disease induces the cerebral mischief. But we are to consider also that the coats of the vessels themselves are weakened by atheroma; while the force of the left ventricle is increased by hypertrophy. The dimness of vision in this disease is owing to an infiltration of the retina and optic nerve with serum. Usually this disease destroys life by apoplexy, or some inflammatory affection; if not, it ends in uræmic poisoning, when head symptoms are prominent, as coma or convulsions, often resembling narcotic poisoning. The brain, after death, is found completely anæmic. Of sixty-eight fatal cases of this granular disease, under the writer's observation, forty-nine had œdema; twenty-four bronchitis; twenty-three hydrothorax; eighteen ascites; eleven uræmic convulsions; fourteen simple coma; thirteen other head symptoms; sixteen pericarditis; seven pneumonia; seventeen vomiting; thirty-one hypertrophy of the heart; fourteen atheroma, and five amaurosis.

Our space will, however, not allow a fuller analysis of the contents of this highly valuable work; we think it will not suffer by comparison with any previous works on this class of affections.

A Treatise on Therapeutics and Pharmacology or Materia Medica. By Geo. B. Wood, M.D., President of the American Philosophical Society; President of the College of Physicians, of Philadelphia; Emeritus Professor of the Theory and Practice of Medicine in the University of Pennsylvania, etc., etc. Third Edition, in two volumes. Philadelphia: J. B. Lippincott & Co. 1868. 8vo., pp. 1800.

It seems hardly necessary to offer a favorable opinion concerning a work like the one before us, in its third edition, but to those of our readers who may have entered the profession within the last seven years, since which time the second edition made its appearance, a brief notice may be necessary.

At the present time, when fashions in medicine lean towards the employment of a very few and pet remedies, and the estimate of general therapeutics is at such a low ebb, it requires no small amount of courage on the part of an author to offer to the profession such a treatise as Dr. Wood's. But the determination to work faithfully in this much-neglected branch, and the desire to do his part in presenting his subject in a properly scientific and sound philosophical light, has surmounted all other obstacles. If the difficulties usually in the way of the physician acquiring a thorough practical knowledge of the action of medicines and of their special uses, has been the cause of ignorance in this department, they are now virtually removed in this masterly treatise. A peculiar value which the work has consists in the embodiment of the author's extensive and valuable experience with almost every article alluded to in the volumes. The manner of treating the various subjects leaves nothing to be desired. Those which are of most importance have a full space allotted them, and the properties of the articles, physical and chemical, adulterations, and therapeutical effects, are admirably and truthfully described. The action of the medicines receives, as it rightly should, especial mention, and the reader is made conscious in his perusal that he is the recipient of views which are marked with the conservatism of a candid teacher. At the risk of being old-fashioned, and even behind the age, he upholds the virtues of those remedies which years ago he proved to himself possessed a practical value; at the same time, with all the ardor of a youthful mind, he studies the effects of the numerous new medicines which have lately been brought to notice. We would gladly take an opportunity to remark upon the merits of the work in extenso, but space not permitting, we have to bring our short notice to a close, by merely enumerating some of the many new substances which are added to and fully discussed in the present edition:—Coca, nitrous oxide, antimoniated hydrogen, gelseminum, calabar bean, bromine and its preparations, lithia and its compounds, ozone, peroxide of hydrogen, permanganate of potash, and sulphurous acid, and the sulphites with carbolic acid in their antizymotic relations.

We have looked over the book carefully, and are not aware that any new article of the slightest possible practical utility has been overlooked, and take this occasion to congratulate our talented and scholarly author for such a faithful performance of a most onerous yet dutiful task.

The author of the volumes before us has well redeemed the reputation of a faithful worker which he has enjoyed for so many years. The work itself is everything that can be asked for as an exponent of sound views and calm philosophical reasoning.

Headaches, their Causes and their Cure. By Henry G. Wright, M.D., M.R.C.S.L., L.S.A., etc. From fourth London Edition. Philadelphia; Lindsay & Blakiston, 1867. 12mo, pp. 154.

This work gives us, in a clear manner, a brief description of all the different marked varieties of headaches, their symptoms and treatment. The varieties are divided into those of childhood and youth, of adult life, depending respectively on the circulating, digestive and nervous systems, gout and organic disease; and lastly of old age. The distinctions between the different kinds of pains in the head are as well drawn as the circumstances will permit, it being very unfortunate for the purpose of a positive diagnosis in each case that the

symptoms of one variety are apt to run into the other. Our author has, however, by a good arrangement of his subject, reduced this difficulty to a minimum. There is an appendix of formulæ, fifty in number, which will be found very useful to the general practitioner.

THE PHYSICIANS' DAILY POCKET RECORD, comprising a Visiting List, Diary, Day-book of Accounts, etc., etc., etc. By S. W. Butler, M.D. Philadelphia: Office Medical and Surgical Reporter, 115 South Seventh street. 1868.

OUR readers are already so wel acquainted with the intrinsic merits of this Record, that it is unnecessary for us to reiterate the opinion which we took occasion to express a few months since.

CHRONIC DISEASES OF THE LARYNX, with special reference to Laryngoscopic Diagnosis and Local Therapeutics. By DR. ADELBERT TOBOLD, Lecturer in the University of Berlin. Translated from the German, and Edited by GEORGE M. BEARD, A.M., M.D., Lecturer in the University of New York. With an Introduction on the History and Art of Laryngoscopy and Rhinoscopy, Rhinitis, Inhalations and Electrization applied to Diseases of the Air Passages, and an Appendix. By the Editor. Illustrated with forty-four wood cuts. 8vo.

EARLY last year, soon after its publication in Berlin, we received a copy of this work in the original, and have had sufficient time to judge of its merits. We were familiar with the author's Manual of Laryngoscopy published in Berlin in 1863, from which the American editor of the present work has largely drawn in the preparation of the volume before us, so as to adapt it as a guide to the use of the laryngoscope, and operative procedure under its reflecting aid, as well as an exposition of the diagnosis and treatment of chronic diseases of the larynx, as modified since the use of the laryngoscope.

The editor begins his introduction with a succinct and correct history of the invention and early applications of the laryngoscope; follows this by a description of Tobold's illuminating apparatus, which we know from ample experience to be the very best and most convenient yet devised; then follows with brief detailed rules of manipulation for purposes of diagnosis and the method of making local applications; proceeds with a description of the art of rhinoscopy, or examination of the nasal passages; follows this with an entirely original chapter on rhinitis; a chapter on inhalation; and concludes with an original chapter on electrization in diseases of the air passages. Then follows the translation; after which appears an appendix by the editor, describing several instrumental appliances not treated of by Tobold, and concluding with a description of the anatomy of the pharynx, uvula, and soft palate. It will thus be seen that the scope of the entire work is very comprehensive, it being evidently the design of the editor to make it complete as a single treatise on laryngoscopy and laryngoscopal medication and surgery.

The editor's originalities consist in the chapters on rhinitis and electricity. With electricity we have not had any experience to justify us in confirming his observations or in dissenting from them; but as his recent efforts in this department of therapeutics are attracting some attention, we are willing to receive his observations with regard to the electrical treatment of laryngeal affections with a certain degree of authority. Rhinitis, or naso-pharyngeal catarrh, or rhinorrhœa, as it has been variously termed, he attributes in the main to confinement in over-heated rooms, and to smoking. We hardly think smoking a prominent predisposing cause, as it is not usually operative in the female, who is the subject of this disease nearly as frequently as the male; nor can we believe that smoking is as often the cause of laryngeal complaints as is the opinion of many, for in ordinary smoking the smoke is not received into the larynx, and when such an inhalation occurs as the result of voluntary effort, the experimenter will find the immediate effect far different from that experienced in the ordinary enjoyment of the weed. We agree with Tobold that exposure to an atmosphere in which many are smoking is directly deleterious, inasmuch as the smoke being diffused in the atmosphere gains ready ingress to the air passages. Dr. Beard recommends the employment of the posterior nasal syringe in preference to Thudicum's apparatus, which is also described, a point upon which our own experience has led to an opposite conclusion. The best remedy for cleansing purposes, he has found to be a saturated solution of chlorate of potash in tepid water, failing with which to effect a curative process, he employs mild astringent and very weak caustic solutions. The article on inhalations is merely a sketch of the subject, and is evidently not intended to be anything more. The editor speaks in the highest terms of electrization as a method of overcoming the irritation produced by caustic applications to the larynx, a method with which we have no experience, and for which we have not as yet found any necessity. We commend this portion of the introduction to the notice of laryngoscopists, for it presents a subject which is of interest, as being new, and doubtless of considerable value.

Being anxious as early as possible to bring to the notice of the profession an English version of this exceedingly valuable treatise on chronic diseases of the larynx, and familiarity with the original work rendering its reperusal unnecessary, we have not critically examined the translation, which, we presume, has been rendered with fidelity and accuracy.

Tobold presents the subject of chronic laryngitis under the division of simple, ulcerative, and tuberculous; each of which subjects, as also the other chronic affections, he treats of systematically under separate headings of anatomico-pathological appearances, symptoms and causes, etiology, laryngoscopic diagnosis, prognosis, and treatment. We would call attention to his insistance upon a distinction between chronic laryngitis and laryngeal phthisis, a view in which with others we accord. In making local applications, Tobold prefers the sponge to the hair pencil in all but exceptional cases of extremely limited ulceration, an experience with which we coincide; and he attributes, in many instances, beneficial results from the mechanical contact of the sponge. He gives the preference as a local remedy in general to nitrate of silver, and next to that, to tannin; and is by no means an advocate for the use of atomized or nebulized fluids. In the local treatment of laryngeal phthisis, however, he gives tannin the preference over nitrate of silver.

The chapters on paralysis of the muscles of the larynx are very interesting. He describes, and depicts diagrammatically, five different forms of paralysis productive of aphonia, in the treatment of which he employs local electrization, not only after the admirable nitro-laryngeal method of Mackenzie, but also by applying one pole over the cervical vertebra and the other over the course of the inferior laryngeal nerve in the groove between the œsophagus and trachea. In hysterical aphonia he employs the electric moxa on the skin in the neighborhood of the larynx. The chapters on foreign bodies in the larynx, and on the detection and removal of neoplasms, are very complete and explicit; and a number of instruments devised by the author for the purpose of surgical interference are described and depicted, the value of most of which we can attest from personal experience.

There are chapters in the work on the histology and physiology of the larynx, and on the physiology of voice. In treating of the latter subject, but two registers are recognized, the chest and falsetto, the head-register being designated as a modification of the falsetto. We are glad of the opportunity this connection gives us to call the attention of the profession to the researches of a lady of Philadelphia, recently of Berlin, who has lately made several discoveries with regard to the physiology of voice, which appear to show conclusively that there are five separate registers of the voice; namely, two of the chest, two of the falsetto, and one of the head, as demonstrable by changes in the form of the glottis recognizable in the transition, by reflection in the laryngoscope. This lady has also demonstrated as the result of numerous dissections, that the cuneiform cartilages mentioned in Wilson's Anatomy, are the chief agents in the production of the head notes, and that they exist much more frequently in the female larynx than in the male larynx, and that this accounts for the inability in the male voice to produce the head notes, except in rare instances. The views of this lady, Madam SEILER, have been received and endorsed by Helmholtz, Du Bois Raymond, Frerichs, and others of high European authority; and she was an assistant of Helmholtz in many of his recent investigations in the production of sound. Mrs. Seiler has now passing through the press of Messrs. Lippincott & Co., of Philadelphia, a work on the culture of the human voice, based upon her own anatomical investigations and experiments with the laryngoscope, which contains chapters on the physiological and physical production of vocal sound, of exceeding interest to physiologists and laryngoscopists, although the book is prepared chiefly with reference to the art of cultivating the voice, and is therefore not intended at all as a medical work; but to the physician interested in the subject of laryngoscopy, and the physiology of the voice, we recommend in advance of its publication a perusal of Mrs. Seiler's forthcoming volume.

The work before us is amply illustrated by wood-cuts, both in the translation and in the additions of the editor; and it will be seen from our remarks that we feel indebted to Dr. Beard for producing this monograph of Tobold in the vernacular, as well as for enhancing its value to the general practitioner by the addition of matter, original and selected, which should render it, in its present form, an excellent guide for the study and practice of laryngoscopy.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, Nov. 27, 1867.

DR. H. B. SANDS, President, in the Chair.

LITHOTOMY.

DR. KRACKOWIZER presented a stone which he had removed about a fortnight ago from a man, sixty-two years of age. The patient came to this country thirty years ago. While in Germany he was a wine merchant, and, although a man of temperate habits, he was obliged to take considerable quantities of wine. He was, however, none the worse for it. When he came to this country he engaged in the clothing business, and became a man of excellent habits. The original symptoms of stone dated back nine years. He sometimes was free from them for half a year, and sometimes longer until the last six weeks, when he was troubled with them oftener, the urine being turbid, and sometimes bloody.

On introducing the sound, the stone was struck immediately. After having satisfied himself as to its presence, the doctor tried to measure its size by drawing the instrument across its surface. It was by this means made out to be an inch in length.

The patient being very fat, the finger could not reach above the upper border of the prostate gland. Dr. K. determined to perform median lithotomy, the operation practised many times by Dr. Markoe. The operation was very easy. He found no difficulty at all in getting into the bladder. The stone, however, could not be grasped to advantage at first, and after repeated attempts it was broken and removed piecemeal. The patient was treated in the same manner as laid down by Dr. Markoe in his paper on this subject in the *N. Y. Medical Journal*. Thirty-six hours after the operation the patient was able to pass a good deal of water through the natural passage; after four or five days it came through only by drops, and on the ninth day, during the passage of two ounces of urine, only eleven drops escaped through the wound. On the eleventh day all the water was passed per urethram.

In conclusion, he would merely state, as had the originator of the operation, that if the stone be too large to be easily extracted, it ought to be broken and taken away in pieces. In this instance he should have followed this advice if it had not been broken by the instruments in the first efforts.

The stone was more or less rounded, was covered with warty excrescences, and was about an inch and a quarter in circumference. It was probably formed of oxalate of lime.

EXTIRPATION OF UTERINE TUMOR.

DR. E. DELAFIELD presented an abdominal tumor on behalf of Dr. Fetter.

"The tumor which I have the pleasure of presenting to the New York Pathological Society, was removed from the person of Mrs. T., of this city, aged fifty-nine years.

"It was removed on the 20th of this month by Dr. Atlee, of Philadelphia.

"The exact particulars of the case at its commencement I am not able to give, but have been informed that the first appearance of the tumor was about ten years since.

"During the last five years it increased very rapidly in size, the great pressure of the same interfering very much with the respiratory and digestive organs.

"The measurement of the abdomen at its largest circumference, previous to the operation, was five feet, and from the sternum to the umbilicus twenty-one inches; from thence to the pubes, fourteen inches.

"Two weeks previous to the operation for removal she was tapped, and sixty pounds of fluid, very thick and purulent, were drawn off, after which she again filled up very rapidly, and on the 20th of the month fifty-two pounds more. The tumor weighed forty-eight pounds, making the weight of the mass, at the time of removal, one hundred pounds, and, with the fluid removed two weeks previous, one hundred and sixty pounds. The fluid drawn off at the time of the operation was highly offensive, and small particles of disorganized matter passed through the opening.

"The walls of the uterus were adhering at every part of the tumor, and it seemed as if it would be impossible to separate them.

"The tumor will be found to be ovarian and also fibrous in its character, and the uterus and both ovaries were involved and removed.

"For twenty-four hours after the operation the patient seemed to be very comfortable; there was no

pain; pulse one hundred and twenty; after which time she commenced to sink very rapidly from exhaustion, and died thirty-six hours after.

"Had the operation been performed before the patient lost her stamina, I think she would in all probability have recovered."

Dr. Krackowizer believed that the tumor was purely a uterine one.

Dr. Buck thought that inasmuch as the discharge at the second tapping was purulent and offensive, it should have been an argument against the operation; and the fœtid discharge at the earlier part of the operation should have put a stop to the proceeding.

Dr. Van Buren cited a case which he saw with Dr. James Anderson some months ago. The patient was a young lady who had an enormous collection of purulent fluid in the cavity of the abdomen. This was drawn off by tapping the cyst. The tumor was afterward removed by Dr. Atlee, and he believed that the result was fatal.

Dr. Cutter remarked that the patient recovered.

Dr. Sayre stated that five or six days after the operation the patient was for some days almost in articulo mortis, but eventually she entirely recovered. In that case there was a discharge of pus at the first tapping.

Dr. Van Buren remarked that he had supposed that the case had proved fatal, as at the last account which he had of it the patient was reported as rapidly sinking.

Dr. Markoe stated that a very important question came up in this connection, viz., what was the effect when the uterus and one or both ovaries were removed?

Dr. Sands remarked that the only experience which he had had was centred in one case operated upon at the New York Hospital. His diagnosis was uterine tumor, and the operation was undertaken with the view of removing the mass. He completed the operation with great difficulty, owing to the attachment of the tumor in the cavity of the pelvis. The case proved fatal a few minutes after the operation. In that instance the uterus and one ovary was removed. The section was made through the cervix uteri, and not through the walls of the vagina.

Dr. Bibbins referred to a case of extirpation of the uterus which had been performed in 1849 in this city. The patient in that instance died upon the table.

SUICIDE WITH MATCHES.

Dr. Finnell exhibited a stomach removed from a young female who destroyed herself by a unique process. Being crossed in some love matters, she made a decoction of half a box of lucifer matches and drank it. She died at the end of six hours.

The specimen, for which he was indebted to Dr. Wooster Beach, Jr., showed a mucous membrane covered with patches of intense congestion and redness.

CANCER OF CALVARIUM.

Dr. Loomis presented the calvarium of a German woman, forty-eight years of age, who died in Charity Hospital on the 4th of November. She had been an inmate of the institution for about two months previous to her decease. Her history was a very meagre one, for the reason that she was not considered dangerously sick until two days before her death. This, in fact, was the first time that Dr. Loomis saw her. Previous to this she was supposed to be suffering from chronic rheumatism. She was complaining of pain along the right arm and in the shoulder, and said that she had suffered from it for the last four or five years. She had been in Bellevue twice for treatment, and had at last been sent from that institution to the Island. The pain was more particularly located by her in the muscles of the back and shoulder. There was a puffiness about the face noticeable, which led to the conjecture that Bright's kidney was present.

On questioning her more closely, she remarked that she had a partial loss of power in her left hand. She had only noticed it the day before, but it had become so rapidly marked that at the examination she was hardly able to raise her hand to her head. The left leg was also found to have lost sensation, and there was also a decrease in temperature. No diagnosis of the case was then made, the doctor supposing that he would have an opportunity to do so after further observation. In the mean time the urine was directed to be examined. At the next visit, three days after, he found that she had died forty-eight hours from the time he saw her; that she grew rapidly worse; that the paralysis increased, commencing in the right arm and extending to the right leg and other parts of her body within the next twenty-four hours. She died quietly. She asked for a drink, spoke intelligently, and when the nurse returned the patient was dead.

The autopsy was made in the absence of Dr. Loomis. All the abdominal and all the thoracic organs were healthy except the heart. This organ was the seat of ossification of the coronary artery. There were also atheromatous deposits in the aorta and on the surface of the aortic valves. These, however, were not insufficient. Some hypertrophy of the left ventricle was also present, which together with the aortic lesion was accounted for during life by the existence of the usual physical signs.

On removing the skull-cap to examine the brain, the gentleman engaged with the saw found that it penetrated different portions of the bone with a great deal of ease; more particularly was this the case with the occipital. This softened condition was explained by a mottled deposit of a new material in different parts of the bone; some of these were of cartilaginous hardness, others of muscular consistency, and others as soft as jelly. This change was confined principally to the occipital bone, parietal bones, and right side of the skull. All the other bones in the body were found in a healthy state; neither were any similar deposits found in any of the soft parts; the muscles, however, had undergone a fatty degeneration.

The microscopical characters of the growths were summed up as follows: fibrous bands crossing polygonal-shaped cells from the $\frac{1}{1500}$ to $\frac{1}{1600}$ of an inch in diameter, with nuclei and nucleoli. These cells were granular, and there were free nuclei everywhere present. In conclusion, he exhibited a drawing of the microscopical appearances, by the gentleman who had made the microscopical examination for him.

Dr. Krackowizer did not think that the drawing was a fair representation of bony cancer, but it seemed to him to be more like osteo-malacia.

Dr. Van Buren, in this connection, referred to the case of a man who had come under his observation, and who on post-mortem examination, presented a skull in a similar condition to Dr. Loomis's patient. The patient died with some vague cerebral symptoms, and the bones of his skull were found infiltrated in places to the thickness of an inch or more, with cheesy cancerous material.

Dr. Terry exhibited a portion of epithelial cancer, which had formed in the cicatrix of a tumor of similar character, removed two and a half months before.

THE EFFECTS OF STRICTURE.

He lastly exhibited the bladder, prostate, and portion of the urethra of a man fifty-nine years of age, who had

gonorrhœa twenty-five years ago, followed almost immediately by symptoms of stricture, and very soon after by complete retention of urine. During the greater part of twenty-three years he was obliged to have the catheter passed. In October, 1865, when Dr. Terry first saw the case, he commenced with a number three bougie, and gradually increased the size of the stricture, until a number eight could be admitted. The patient then absented himself until the stricture closed again, when he returned. This he did three or four different times, when the same process of dilatation was resorted to.

The patient died a short time ago, and Dr. Terry obtained possession of the specimen. The walls of the bladder were very much thickened as the result of chronic cystitis. The stricture in the spongy tissue was a long and firm one, divided into two sections, and at the time of death would hardly admit a number four probe. He died of cystitis.

Dr. Post thought that the dilatation could have been carried on still further, and might have relieved the patient perhaps permanently.

Dr. Terry remarked that he would have persevered, but the patient refused to bear the necessary punishment.

The Society then adjourned.

Correspondence.

MEDICAL MATTERS IN PARIS.

(FROM OUR SPECIAL CORRESPONDENT.)

To the Editor of the Medical Record.

Sir—You will remember, no doubt, that at the International Congress the theme which opened the debates, and which occupied a most prominent place in the discussions, was the apparently exhausted subject of tuberculosis. M. Villemin has just offered to the Academy the treatise of which his remarks at the Congress were the abstract, the exposition, and the defence. The researches of this ingenious experimentalist have led him to conclusions differing so widely from those generally adopted, as to excite the curiosity, applause, or indignation of every defender of the medical faith. Hence the report of M. Colin on Villemin's book has been followed by an able and lively discussion of unexpected interest in connection with a disease which had, so to speak, fallen into disuse, and whose victims were regarded as useless incumbrances of the clinical wards in the hospitals.

INOCULABILITY OF TUBERCLE.

The novelty of Villemin's views is manifested on three important points. 1st. Denying the existence of epithelium in the pulmonary alveoli, the physician of Vâl-de-Grace contradicts Reinhardt's assurance that the cheesy masses occupy the air-cells, and ascribes to them the same origin and seat as that generally admitted for the gray granulations, viz. the connective tissue between the alveoli, and around the blood-vessels. These masses are the result of fatty degeneration of the plasmatic elements of the connective tissue, whose proliferation has given rise to the nuclei and small cells characteristic of the centre of the gray tubercle. These last elements invariably degenerate, but not unfrequently the large connective cells on the periphery of the granulation are also invaded while yet undergoing the process of multiplication. In this respect, therefore, Villemin returns squarely to the views of Laennec, who regarded the cheesy masses as softened tubercles.

2d. The most remarkable part of the *Etudes sur la Tuberculose* is that which relates to the experiments on inoculation of tuberculous matter, some of whose results were submitted to the Academy in 1865. Villemin was induced to make these experiments, by observing the histological resemblance of the elements of the miliary tubercle with those of the tubercle of syphilis or glanders. Since they were specific and inoculable, he inferred that the gray granulation might be so as well. The second half of this supposition has been fully confirmed. An immense number of experiments have been performed upon rabbits, by inserting into the subcutaneous cellular tissue fragments of pulmonary tubercles, and in nearly all cases the injection was followed by an eruption of miliary granulations in the lungs, and by the constitutional symptoms of tuberculosis, to which, after awhile, the animals succumbed.

3d. Upon the success of these experiments, the first of any consequence that have ever been made in this direction, M. Villemin bases an entirely new theory of tuberculosis. He claims that what is inoculable must be specific; that tuberculosis belongs, in its character of specificity, to a family of diseases, depending on the substantial introduction into the system of a peculiar animal virus. It is, in short, a definite, virulent, contagious disease, like syphilis and glanders; and the histological similarity between the tumors in the three cases is justified, so to speak, by their family or generic affinity.

Now, as to the reality of the results obtained by M. Villemin in his experiments, there can be no doubt. They have been repeated with equal success by M. Colin, who reports the new treatise to the Academy; their accuracy is acknowledged by M. Cornil, from whose party Villemin has made such a frightful secession. Bouchard, in his review in the *Gazette Hebdomadaire*, and Chauffard and Pidoux in their speeches at the Academy, all admit this striking and unexpected discovery—viz. that tuberculosis, anatomically and clinically characteristic, may be communicated to rabbits and guinea-pigs by inoculation from the tubercles of cattle or human beings.

But the inferences adopted by M. Villemin are extremely contestable and contested, as M. Chauffard by an anatomical, M. Pidoux by a general analysis, successfully disproved the pretended virulence of the tubercular deposit. Chauffard points out that inoculations of specific animal poisons, as those of syphilis, small-pox, hydrophobia, etc., are first made with fluids containing no morphological elements or special characteristics. But Villemin's favorite experiments consisted in *grafting* a definite structure upon the organism. When this structure, sown on soil rendered congenial by the presence of lymphatics, develops itself and excites the surrounding tissues to similar proliferation, it does so in virtue of the laws of development of tumors, which, according to Virchow, depend on the foundation of a tissue by elements coming from another tissue.

2d. A definite period of incubation is essential to the process of virulent inoculation; after which appears local trouble, speedily followed by general symptoms of infection. But M. Colin shows that in the experiments there is no such incubation, and no reproduction of the tubercle on the place where it was inoculated. The tumefaction observed there results from the resistance offered by the tubercle to the dissolving action of altered pus, on account of which some of the matter originally introduced may often be found on the same spot six weeks afterwards. M. Pidoux declares that the tubercle, placed at the base of the scale of heteroplastic formations, multiplying like all inferior organisms, dying speedily, and infecting the locality

with products of decomposition, is in the highest degree incapable of the incubating force, the latent and refractory vitality characteristic of virus.

3d. The gray granulations are possessed of no exclusive power of infection. Villemin himself has produced an eruption of miliary tubercles by inoculation of the cheesy detritus, and even admits this to be the most favorable for the experiment. It is on this fact that he bases the revival of the doctrine of identity between the cheesy mass and the crude tubercle. M. Colin has successfully inoculated various animals, rabbits, guinea-pigs, lambs, calves, and dogs, not only with the cheesy deposit, but with the hard cretaceous tubercle from the lungs of oxen. Clarck has succeeded with ordinary pus; and Empis with pus from puerperal peritonitis, from the surface of Peyer's patches ulcerated in typhoid fever, and from suppurating fibrinous pneumonia. Finally, Lebert has experimented with mineral substances, as mercury and carbon. In all these cases a crop of perfectly characteristic gray, hard, semi-transparent tubercles was obtained in the lungs of the animals submitted to the experiment. It is impossible to imagine a more complete demonstration of the *common* and non-specific origin of the crude tubercle.

4th. M. Colin, in his report, follows step by step the consequences of the inoculations, and shows that for a long time they are purely local. The disease is communicated, not by the general infection of the whole system, but by the implantation of a thorn, whose irritation gradually extends and involves the lungs. The focus of inoculation is presently surrounded by radiating white lines, formed by lymphatic vessels engorged with foreign matters. The ganglia in which these vessels terminate engorge themselves also, and become filled with tubercular granulations, and others in their turn. The ganglia not found on the route traversed by the morbid vessels, remain perfectly sound. From the lymphatic system, the tuberculous matter gains the central organs, probably by the route of the circulation, and is thus gradually deposited in the lungs, liver, spleen, and kidneys. This evolution is exactly that of the gradual propagation of a local evil, not the simultaneous impregnation of the entire organism by a virulent agent.

Colin is so impressed by this local character of the disease artificially produced, that he jumps to the conclusion that natural phthisis is also the result of local mischief, resulting from one or more tubercles that have at some time been introduced into the economy, and after remaining latent for an indefinite period, are suddenly awakened to activity. But this supposition is entirely gratuitous.

5th. M. Pidoux dwells upon Villemin's admission that the yellow tuberculous matter is more active than the gray tubercle. If we assume (which, as we shall presently see, is conceding too much) that this cheesy deposit be in fact a degeneration of the tubercle, a striking contrast becomes apparent between the tubercle and virus. This is more active in its first stages than at the period of its degeneration.

6th. Pidoux also observes that the similarity between the histological structure of the tuberculous tumor and of syphilis and glanders, is really an argument *against* the virulent character of the first affection. For at the moment that the other two diseases have resulted in tumors, they have ceased to be virulent, and have passed into a state of diathesis. Inoculation from those tumors will give rise to neither glanders nor syphilis. Hence this grand foundation-stone of the new theory, and this initial observation of M. Villemin's researches, is wrenched from him, and turned most ingeniously into a powerful argument against his cause.

From this *critique* it appears that inoculation of tuberculous or other matter acts on the lungs (whither it has been brought by the blood, and arrested by the fine network of capillaries), by irritation of the plasmatic cells of the connective tissue. These, proliferating, give rise to the small elements, which, closely crowded together, constitute the gray tubercle. The process is closely analogous to the proliferation of inflammation, which also results in the formation of the small cells and nuclei of pus, which cannot by their form be distinguished from those of the crude tubercle. The difference consists—first, in the intercellular substance, liquid in pus, finely granular in the tubercle; second, in that the fatty degeneration results in cheesy masses for the tubercle, while the pus remains liquid.

In all cases of artificially induced disease the irritation comes, of course, from without, and may be called local. This may occur also, as Pidoux observes, in acquired phthisis, especially in that of miners and others constantly exposed to direct irritation of the lungs. But in constitutional and hereditary consumption the tubercular process is to be regarded simply as the final stage to which all irritative processes in weakly subjects naturally tend to degenerate.

"The impoverishment of the field of nutrition is the first condition of tuberculosis," says Pidoux; "the occurrence of some irritation the second. Nothing is more susceptible of irritation than weakness, nothing so ready to degenerate." Again (for I quote willingly from this able and brilliant discourse in which he old colleague of Trousseau so well justifies his reputation), "tuberculosis is the constitutional alteration, the characteristic and organic heteroplasia of the lymphatic apparatus, the fundamental apparatus of nutrition. This is attacked in the connective tissue, which constitutes its base. When this tissue sustains what Hunter calls the *stimulus of imperfection*, it is excited to proliferations, imperfect, sickly, of an extremely ephemeral vitality, born in fact but to die; such is the tubercle."

Chauffard ingeniously suggests that the ease with which the tubercle may be inoculated depends precisely upon the poverty of its organization. The fecundating tissue, to refer again to Virchow's idea and expression, would need to make less effort to assimilate another to a feebly organized structure, than to one complex, rich, and characteristic; and from this point of view the inoculation of tubercle is more easily comprehensible than that of cancer.

But the existence of an internal cause for tuberculosis, of a diathesis and of hereditary tendency, is denied by M. Villemin, and it is this denial that constitutes the fame of his heresy. He is as frank a believer in the contagious origin of phthisis as a doctor of the sixteenth century, or an Italian or Spanish peasant of the present day. For him *réunions* of consumptives constitute more deadly foci of infection than cholera hospitals, and the lives of the patients sent to Nice and Cannes are terribly shortened by the atmosphere impregnated with emanations from the reeking lungs of their fellow-sufferers.

Upon this point especially does M. Pidoux attack the innovator. He charges him, not unfairly, with having entirely neglected the clinical study of tuberculosis in his absorption in its anatomical pathology. Examination of lungs after death is extremely useful as a means of ascertaining the results of disease and many of its processes, but must usually be incompetent to determine its cause. And it is glaringly illogical to conclude that because in a given case a disease has been artificially produced by inoculation of certain substances from without, therefore all spontaneous cases of the af-

fection depended on the same mechanism. As well argue that capillary bronchitis could only be caused by injection of snuff into the trachea.

Yet precisely to this complexion has come M. Villemin. He formally denies the possibility of any spontaneous alteration of the organism, and insists that all disease must result from the infliction of exterior agents. Thus, from the reformed basis of phthisis, he dares attempt the reform of all pathology. But, as Pidoux observes, all exterior agents would be without effect were it not for a susceptibility on the part of the organism to be affected, which capacity itself constitutes a spontaneity and individuality.

In the meantime M. Pidoux is far from claiming for phthisis that overwhelmingly predestined character with which it is popularly associated. He admits that about one-sixth of all consumptive patients contract the disease in virtue of direct hereditary influence, but that many others are predisposed on account of *transformed* hereditary influence; arthritism, herpetism, syphilis, or scrofula in the parents, tending less to reproduce themselves in the children than to occasion pulmonary tuberculosis.

Similarly, phthisis springs up in the wake of many diseases, which at their height are directly antagonistic to it. This is the case especially with arthritism, whose remains seem as it were to enrich the soil of the economy, and prepare it for phthisis. Such transformation takes place with the same individual. But in hereditary transmission M. Pidoux announces as a sufficiently definite law, the progress of capital or initial diseases, first towards mixed diseases, then those that are ultimate or organic. Thus arthritism, scrofula, syphilis, capital diseases, change into herpetism, neuroses, neuralgias, catarrhs, etc., or mixed diseases; and these in turn degenerate into organic diseases, as tuberculosis, cancer, epilepsy, and incurable degenerations of the nervous centres. M. Villemin entirely denies any connection between scrofula and tuberculosis, which is the more singular as he cannot ignore the readiness with which the lymphatic glands become the seat of cheesy degenerations, such as he identifies with tubercle. It is precisely because he is forced to admit the multiple origin of scrofula, that he seeks to separate it from tuberculosis, of which the specific character must be preserved at all hazards. Pidoux, fully conceding the difference between the two diseases, justly insists on their frequent etiological connections. Scrofula is the initial chronic disease, often superficial, curable, and not an organic malady, although capable of becoming so. Tuberculosis, and especially pulmonary phthisis, are ultimate and organic diseases, too often the final stage of non-tuberculous affection. It is quite as necessary for scrofula as for arthritism or syphilis to degenerate before it gives rise to tuberculosis; patients with scrofulous ulcers are not consumptive, but lymphatic constitutions, delicate, nervous, "civilized," fall an easy prey to phthisis, often because of their escape from the external manifestations of the disease.

Finally, it is unquestionable that a number of persons untainted by hereditary vice of constitution, and uninjured by previous disease, fall victims to consumption on account of exposure to cold, to want, to privations. Pidoux seems to imply that in these cases the disease commences in bronchitis, determining proliferations of alveolar epithelium, which degenerates into cheesy masses, which ultimately excite a crop of tubercles by irritation of the connective tissue. Pidoux, therefore, fully admits the German distinction between pneumonic phthisis and granular phthisis; the last being constitutional, the first accidental, and often extremely rapid. Bouchard adheres also to this view, and sums up the differences between the gray tubercle and yellow masses, which nearly, if not quite, demonstrate their independence of origin. In the first stages of the "cheesy pneumonia," as the yellow masses are called by the new-school pathologists, the alveoli are found partially filled with large pavement cells, which, in spite of M. Villemin's assertions, reveal their epithelial character by being more or less soldered together. The alveoli also contain serous exudation. On the contrary, the first stage of the granulation consists of a mass of small spheric cells, 0^{mm}, 008 in diameter, with the nucleus filling the cavity almost completely, closely pressed against each other. This mass is situated, not in the alveoli, but in the connective tissue at the bifurcation of the blood-vessels. In the second stage of catarrhal pneumonia the liquid is absorbed, the anatomical elements accumulate and become infiltrated with fat, and presently the alveoli are rendered entirely impermeable to the air, and offer on section a smooth level surface uniformly gray and homogeneous. The granulations also submit to the cheesy degeneration, but for a long time retain their form, so that different zones are distinguishable in their mass.

Villemin's second thesis, therefore, which constitutes his remarkable discovery, is everywhere confirmed, and it is an acquired fact that it is possible to produce pulmonary phthisis artificially, by inoculation with tubercular deposit, or with the products of the pneumonia accompanying, determining, or determined by that deposit. But his first theory, that identifies the tubercle and the pneumonia, and his third, which would make of phthisis a specific virulent disease, seem to be sufficiently refutable and refuted.

I only mention in passing the theory of contagion, for that is confessedly based on no clinical facts, but those dubious ones that have already done service for this theory. M. Villemin seems to infer that the contagion of phthisis must be a necessary consequence of its inoculability. But this is evidently a strained conclusion, since the conceivable mode of transmission between human beings must be widely different from that practised by Villemin on his rabbits. The hateful practical consequences of this doctrine of contagion may justify, perhaps, a partiality for M. Pidoux's vehement denunciation of its possibility. I have ventured to devote so much space to this discussion (of which I have endeavored to render the substance, but have been unable to transfer the zest and animation), because it is one of the most important that has taken place in Paris for some time. The daily urgent practical need of interest in pulmonary consumption is so great that even a scientific vagary that should rouse the flagging attention to a worn-out theme, would be of value. This book of M. Villemin's, however, is no vagary or frivolity, as you may judge from the elaborate report that has been made of it to the Academy, and from the spirited debate to which it has given rise. But, in spite of its ability, and the great interest of the experimental researches, it is a reaction in a sorrowful direction. All hopes of curing phthisis depend upon its nature as a general disease of common origin; and the theory which tends to make it specific condemns the physician to inertia, or the vain revival of forgotten specific antidotes. It is with pleasure, therefore, that I find that M. Villemin's arguments are less sound than they are brilliant, imposing, and endowed with the charm of novelty. P. C. M.

PARIS, January 2, 1868.

A RUSSIAN FEMALE PHYSICIAN.—A young Russian lady has just passed her examination as Doctor of Medicine at the University of Lubeck.

DECOLORATION OF IODINE.

To the Editor of the Medical Record.

Sir—During some experiments on iodine, I recently discovered a fact to which I desire to call the attention of the profession.

It has long been a desideratum in therapeutics to deprive the tr. iodine, a remedy of so much value in external and local medication, of the objectionable stain which it leaves on the skin and linen of the patient. The latter is especially complained of by patients for whom this substance is prescribed as lotion, injection, or liniment.

In the skin department of the Demilt Dispensary, Dr. Bluxome was (in 1865) in the habit of using tr. iodine, decolorized by liq. ammoniæ. But as this combination appeared so very irritating as to cause children, to whom it was applied for herpes, etc., to scream most violently, Dr. B. concluded to abandon its use rather than inflict unnecessary pain on his little patients.

Recently (Nov. 1st) your journal contained a notice of the decolorizing property of carbolic acid on iodine, discovered by Dr. Percy Boulton. This "carbolate of iodine" is highly praised in a letter to the *Journal des Connaissances Médicales* as an antiseptic and stimulant, and as such it is doubtless a valuable agent. But in some cases the carbolic acid might be contra-indicated.

I have ascertained that the hyposulphite of soda has the peculiar effect of depriving the iodine of its color, forming a perfectly limpid fluid, which does not form the purple iodide of starch on the linen, nor produce the yellow discoloration of the skin. The hyposulphite having no medicinal effect in the small quantity required for this purpose, the tr. iodine suffers no addition to nor detraction from its therapeutic properties.

I make a saturated solution of the hyposulphite in water, and this is added in proportion of about one-sixth of the tr. iodine. The latter floats upon the former, but through agitation will produce a beautifully clear solution with the properties mentioned.

The solution of the bisulphite answers the same purpose.

If we desire to obtain the effect of the undiluted tr. iodine, we need only dissolve a few small crystals of the hyposulphite, or a little of the powder of the bisulphite in the tincture, and complete decoloration will be the result.

S. Baruch, M.D.

Camden, S. C., Feb. 1, 1868.

BROMIDE OF POTASSIUM IN FUNCTIONAL EPILEPSY.

To the Editor of the Medical Record.

Sir,—I take this occasion to report the following case of *apparent* cure of epilepsy by bromide of potassium:—The subject, a young lady about twenty-five years of age, applied to me a little over a year ago, to know if anything could be done to relieve her from her disease, which she stated had existed for several years; the fits occurring every two or three weeks. On examination, no cause could be found to account for them, and I gave her but very little encouragement as to the result of treatment. Having seen accounts of the action of the bromide in such cases, I mentioned it to her, and she concluded to try it. She has done so from that time to the present, and the result has been, that it is now one year since she has had an attack of the disease. I have delayed reporting the case till now, that I might be sure that the remedy was producing the effect. I have two other cases of epilepsy under the same treatment, and when they have been treated long enough I will report. I have used the bromide in several cases of nervous restlessness, particularly at night, caused by uterine disease, and have derived much benefit from it.

The formula used in the case of epilepsy reported above was as follows:—

℞. Pot. Bromid. ʒ vi.
Ammo. Bromid. ɔ ij.
Pot. B. Carb. grs. xv.
Tinc. Columbo ℥ iss.
Aqua ʒ iij.

Teaspoonful three times daily before eating.

I am, sir, yours respectfully,
Josiah F. Day, M.D.

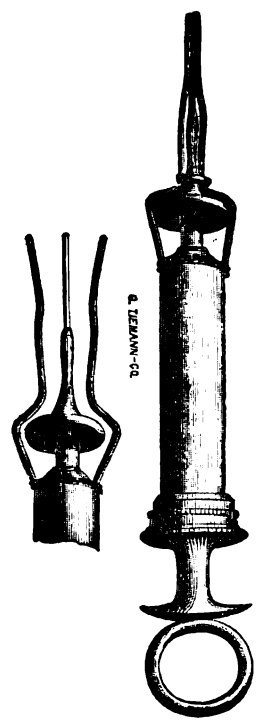
Alfred, Maine, Feb. 1868.

New Instruments.

A NEW SYRINGE FOR THE TREATMENT OF GONORRHŒA.

By M. S. BUTTLES, M.D.,
Adjunct to Chair of Obstetrics, University Medical College, New York.

The accompanying cut represents a syringe made for us, about two years ago, by Messrs. Otto & Reynders, for the treatment of urethritis. The nozzle of the syringe is surrounded by two prongs, so arranged as to admit of being opened by means of a ring or button. The syringe being loaded with a medicated solution, the nozzle with the prongs is introduced into the urethra. The prongs are then separated by means of the ring, so as to dilate the urethra, or rather to put the mucous membrane on the stretch, after which the injection is thrown in, thereby washing out and effectually touching every part of the diseased surface.



By the use of this syringe, with a weak injection, we have cured more than a score of obstinate cases of

gonorrhœa and gleet, which had resisted all the treatment our ingenuity could suggest.

We would recommend this instrument to the profession as specially applicable in chronic cases, in which the inflammation burrows in the folds of the mucous membrane, which ordinary injections or medicines (passing out through the urine) do not, and cannot reach.

We have made some improvements which facilitate the working of this syringe that this cut does not represent, but which we doubt not every intelligent physician will quickly comprehend when he comes to practically apply one of the improved instruments.

Medical Items and News.

PROF. JOSEPH JONES, OF NASHVILLE.—We are pained to hear that the residence of Prof. Jones was recently destroyed by fire, together with many of his most valuable manuscripts.

PROF. AUGUST V. VOGEL.—We notice, in recent exchanges, the death of the celebrated German Chemist, Prof. August v. Vogel, M.D., in his ninetieth year, up to which advanced age he retained the fullest vigor of body and mind. He was the oldest member of the Munich Academy of Sciences, and was particularly distinguished for his analyses of the various mineral waters in his native kingdom of Bavaria.

CHASSEPOT WOUNDS.—Several physicians, who participated in the late Garibaldian campaign, express themselves as follows with regard to the effects of the new chassepot gun. The multitude of missiles which can be scattered over the battle-field in the course of a few minutes, by means of this fire-arm, unquestionably has the effect of putting a large number of troops *hors de combat;* but, by reason of the small size of the projectile, the number of fatal injuries is very small in proportion to the total number of wounded.

It has been established, on observation of the wounded at Mentana and elsewhere, that the Chassepot bullet rarely shatters a bone, but, in the large majority of cases, passes around it..—*Allgemeine Wiener Zeitung.*

CIRCULAR No. 5—SURGEON-GENERAL'S OFFICE—REPORT ON CHOLERA.—Dr. Crane, Assistant Surgeon-General U. S. A., has presented to the King of Prussia a comprehensive report of the course of the late cholera epidemic amongst the U.S. troops. This admirable work has created great interest, and been highly appreciated in military medical circles. The Russian Minister in Washington has received instructions to convey the thanks of the King to Assistant Surgeon-General Crane for this valuable work.—*Allgemeine Med. Central-Zeitung, Berlin.*

Professor ROKITAUSKY, of world-wide reputation, has recently been appointed life-member of the *Herrenhaus*, or House of Lords, of Austria. This recognition of the merit of a professional brother seems to excite the liveliest sentiments of satisfaction in the German medical world, and congratulatory addresses pour in on every side unto the newly made Peer.

PROF. JOSEPH GRUBER.—At a late session of the College of Professors of Vienna, Prof. Hyrtl, one of the first celebrities of our University, proposed, in an able written address, the name of Dr. Joseph Gruber as extraordinary Professor of Aural Medicine and Surgery, on the ground of the high literary attainments of this gentleman, and especially of the great value of his late work on the Membrana Tympani. Dr. Gruber, in view of his valuable services to the public, thousands of whom, every year, had received gratuitous advice from him on diseases of the ear, was recently appointed attending surgeon to the Imperial General Hospital.—*Wiener Medicinische Zeitung.*

OUR GREAT MASTERS.—Dr. B. W. Richardson, of London, in the course of an address on *Research in Medicine*, delivered to the Saint Andrew's Medical Graduates' Association, makes the following eloquent allusion to the few great masters in medicine:—"So great is this limitation that the twenty-three centuries from the Father of Medicine have not brought twenty masters who at this moment are powerful to command. Hippocrates still holds out the natural history of disease; Paulus remains the foundation-stone of surgery; Paracelsus keeps the crucible; Vesalius as yet is the anatomist; Harvey still has his hand on the engine of the circulation; Willis is opening the skull-case and unrolling the brain; Mayo continues to teach that there is a furnace in the animal body burning by the air; Black and Priestley tell the nature of the combustion; Haller adds physics to physic, and Boerhaave scientific chemistry. Pinel puts the psychical upon the physical; John Hunter links the physiology of animals inferior to that of the animal superior; Jenner stands out alone the revealer of a wholesome remedy; Humphry Davy, escaping from his nitrous oxide box, and exclaiming to Dr. Kinglake, 'Nothing exists but thoughts, the universe is composed of impressions, ideas, pleasures, and pains,'—leads the beneficent advance of those who have abolished the horror of the surgeon's knife; and Laennec, pronouncing a diagnostic on such safe physical basis as to leave no improvement on his principles, heads the last of the

> "'Tongues of our dead not lost,
> But speaking from death's frost
> Like fiery tongues at Pentecost.'"

HYPODERMIC INJECTIONS OF MORPHINE, to the number of two hundred weekly, are employed in the cancer wards of the Middlesex Hospital.

M. BRUNETTI, whose method for tanning anatomical preparations has recently been presented to our readers, has obtained a patent for the same.

CONTRIBUTIONS TO MEDICAL JOURNALS.—DR. T. PARVIN, the accomplished editor of the *Western Journal of Medicine*, in remarking upon our recent leader on Medical Authorship, makes the following pertinent comment:—"We have now at least a dozen articles, received within six months, which we will be glad to publish when time occurs for revision. Sometimes, however, such revision costs a subscriber, for there are some men who, actuated by benevolence or love of small notoriety, will send articles abounding in the grossest violations of orthography and syntax—violations such as a child of ten years, who has been properly educated, would not make, and in complicated and involved sentences; and when these articles, subjected to competent medical revision, are rewritten in good English and then published, become virtuously indignant and 'stop the *Journal*.' Publish such an article as sent, and the offence is equally great or greater, and at the same time you disgrace your periodical; decline publishing, and the would-be contributor is just as indignant, and thinks your *Journal* is a poor thing. How can we escape Scylla without running against Charybdis?"

ACKNOWLEDGMENT.—The managers of the Nursery and Child's Hospital of this city acknowledge the donation of five thousand dollars from the estate of the late Chauncey Rose.

Garratt, Dr. A. C., review of work by, 62.
Gentian root as a dilator, 491.
Glottis, case of spasm of, 140.
Gonorrhœa, treatment of, 108.
Gorilla, anatomy of the, 240.
Goodwillie, Dr. D. H., a new inhaler, 453.
Grosvenor, Dr. J. W., inflammation of psoas magnus, 435.
Gross, Dr. S. D., clinics of, 82, 105, 249, 273, 342; on tumors, 487, 512.
Greene, Dr. W. W., fibrous tumors of uterus, 52; removal of deep cervical tumor, 173.

H.

Hachenberg, Dr. G. P., chloroform as a vaporizer, 381; extirpation of uterus, 505.
Hæmorrhagic diathesis, hereditary tendency to, 19.
Hair, blanching of the, 180.
Hamilton, Dr. F. H., bullet in heart, 18; lectures by, 151, 224.
Hamilton, Dr. L. A., strychnine poisoning treated by chloroform, 23.
Hare-lip, lectures on operations for, 151, 224.
Hart, Dr. John, obituary notice of, 335.
Hartshorne, Dr. H., review of work by, 329.
Heat, as a resuscitating agent, 10.
Heart, bullet in for twenty years, 18; case of rupture of, 412; wound of, 232; diseases of, 104, 154, 299.
Hæmorrhoids, a new instrument for, 215.
Hepatic abscess, cases of, 241.
Hernia, case of mesenteric, 111; coffee in, 420; vomiting after reduction of, 260; ether spray in, 228; umbilical, treatment of, 316.
Herpes circinnatus from achorion in mouse, 337.
Herzog, Dr. M., causes of cholera, 193.
Hip-joint; disease, treatment of, 289; amputation of, 266.
Homœopaths, consultations with, 430; and retained placenta, 399.
Hooker, Dr. Worthington, obituary notice of, 453.
Hospital practice, remarks on, 206, 325, 489.
"House-maid's knee," pathology of, 210.
How does a young physician get into practice? 38.
Howard, Dr. B., letter from, 189; on ligatures, 449.
Hudson, Dr. E. D., Syme's amputation at ankle-joint, 40.
Human life, economy of, 284.
Hutchison, Dr. J. C., aneurism of arteria innominata, 265.
Hydrogen, process for producing, 466.
Hydrocyanic acid, experiments with, 457.
Hypodermic syringe, description of a new, 502.

I.

Indigestions, review of work on, 87.
Infanticide, a legal question regarding, 236.
Infantile paralysis, review of work on, 134.
Inhalation, review of work on, 471.
Inhaler, a new, 453.
Insane, effect of music on the, 440.
International Medical Congress, remarks on, 351, 373, 376, 557.
Iodine, removal of stains produced thereby, 391.
Ireland, medical examination in, 431.
"Is he reliable?" 493.

J.

Jefferson Medical College reports, 82, 105, 249, 273, 342.
Jobert (de Lamballe), obituary notice of, 190.
Jones, Dr. Joseph, experiments with hydrocyanic acid, 457.

K.

Kidneys, malposition of the, 228.

Knee-joint, amputation at, 185, 258; operation for anchylosis of, 63; repeated resection in, 84.
Krackowizer, Dr. E., discharge of worms per urethram, 174; extirpation of uterus, 297.

L.

Lake Michigan, tunnel under, 143.
Lawton, Dr. J. W., discoverer of anæsthesia, 382.
Lawson, Dr. F. B., uterine applicator, 478.
Lawson, Dr. Geo., review of work by, 375.
Laryngoscopy, 4, 29, 294, 313, 385, 569.
Lawrence, Sir William, death of, 287.
Lecture term, extension of, 229.
Letterman, Dr. J., review of work by, 39.
Leute, Dr. F. D., new method for facilitating operation for badly united fracture, 101.
Leprosy, case of, 372.
Lewis, Dr. W. B., rupture of the heart, 412; pathology of urinary organs, 506.
Ligatures, remarks on, 60, 449, 525.
Lister, Dr. J., carbolic acid putty, 396.
Lithotomy, cases of, 355, 468.
Liver, cancer of, 256, 369; rupture of, 111; tuberculous diseases of, 232.
Long Island College Hospital reports, 104, 154.
Loomis, Dr. A. L., physical exploration of abdomen, 388, 438, 534.
Lower jaw, new mode of treating fracture of, 324.
Lunacy, review of reports on in France, 14.
Lung, treatment of hæmorrhage from, 534.
Lyman, Dr. H. M., letters from, 68.

M.

Malarial fever, quinine as a preventive, 228.
Malpractice, duties of a medical witness in, 474.
Mammary gland in the male, 231.
Marsh, Dr. E. J., Cæsarean section by a cow, 148.
Maudsley, Dr. H., review of work by, 423.
Maury, Dr. R. B., hepatic abscess, 241.
Maxilla, removal of osseous tumor from superior, 145.
Measles, prophylaxis of, 260.
McClellan, Dr. E, chloroform as a therapeutic agent, 219.
Medical; advertising, 39, 95, 371; cliquism, 349; evidence in law, 183; schools, examination for, 181; teachers' convention, 85, 130.
Medical Society; of County of New York, 89, 112, 139, 368, 417, 498; of State of New York, report of, 553.
Medicines, our knowledge of, 44.
Medico-legal Society, organization of, 301.
Medulla oblongata, action of hydrocyanic acid on, 457.
Meigs, Prof. C. D., review of work by, 159.
Meningeal apoplexy in new-born, 112.
Menorrhagia, treatment of, 251, 321.
Menstruation in the male, 83.
Mental labor and physical exertion, 432.
Merrill, Dr. A. P., biberine in uterine disease, 7.
Methylene, bichloride of, 466.
Metropolitan Board of Health, 374.
Mica, new uses for, 311.
Midwives, a call for, 470.
Milk, breast, prejudices against, 180.
Mind, review of book on physiology and pathology of, 423.
Minié-ball, expectoration of, 179.
Monster, anomalies in a, 283.
Morbus coxarius, resection of femur for, 17.
Morgan, Dr. Chas. E., anatomy and physiology of skin, 73; obituary notice of, 311.
Muscular fibre, contractility of, 307.
Muscular force, production of, 247.
Muscles, contracted treatment of, 418.
Myrbane, poison by, 455.

N.

Nerves, emotional disorders, review of work on, 426.
New York Academy of Medicine reports, 41, 95, 163, 183, 284, 344, 368, 451, 472, 499, 519.
New York Hospital reports, 514.
New York Medical Journal Association, 40, 499, 523.
New York Medico-legal Society, 403, 474, 499, 545.
New York Pathological Society reports, 17, 63, 88, 112, 135, 160, 185, 207, 231, 256, 283, 302, 320, 299, 413, 448, 475, 497, 525, 544, 570.
Nitrous oxide as an anæsthetic, 77.
Nursing, artificial, consequences of, 400.

O.

Obstetrics, review of work on, 159.
Old folks, number of, 220.
Ogden, Dr. Benj., obituary notice of, 215.
Os uteri, case of occlusion of, 323.
Os calcis, case of excision of, 171.
Osteomyelitis, case of, 257.
Ophthalmoscope and renal disease, 135.
Ophthalmological Society, review of transactions of, 182.
Opium in therapeutics, 300, 371.
Operations, over-eating as a risk in, 391.
Our therapeutics, 13.
Ovariotomy, cases of, 70, 192, 207, 213, 231, 245, 268, 356, 519.

P.

Paralysis, electricity in, 148, 361.
Parker, Dr. Willard, operation for abscess of appendix vermiformis, 25; ligature of subclavian artery, 97.
Paris, medical matters in, 212, 303, 351, 376, 476, 501, 547, 572.
Patella, treatment of fractures of, 198, 221.
Pericardium, rupture of, 400; needle in, 119.
Philadelphia County Medical Society, 42, 92, 165.
Philadelphia, medical matters in, 187, 234, 356, 427.
Phthisis; in Barbadoes, 323; mode of propagating, 466; raw flesh in, 394.
Phymosis, congenital, and epilepsy, 444.
Physician, novel mode of swindling a, 212.
Physical exercise, abuse of, 432.
Pinkney, Dr. H., artificial anus, 223.
Placenta, retained, homœopathic treatment of, 399.
Pleurisy in infant, 19.
Pneumonia, cases of abscesses, following, 226.
Poisons, animal, causes of activity of, 391; review of work on, 425.
Pomeroy, Dr. O. D., chloroform in suicide, 55; use of Eustachian tube, 317; Eustachian catheter-holder, 403.
Poor-houses, condition of in New Jersey, 216.
Post, Dr. A. C., morbid affections of fingers and toes, 201, abscess, 318.
Post-mortem needles, new, descriptions of, 238, 333.
Prescriptions, remarks on, 353, 421.
Prescriptions and their ownership, 261, 470.
Prognosis, uncertainties of, 397.
Prolapsus uteri, electricity in, 169.
Prostate, inflammation of, arsenic in, 227.
Pruritus pudendi, remedy for, 11, 492.
Psoas magnus muscle, acute inflammation of, 435.
Puerperal convulsions, remarks on, 8, 32, 252, 299.

R.

Rachitis, treatment of, 371.
Radius and ulna, complete lateral luxation outwards, 387.
Railroad collisions, prevention of, 504.
Railway injuries, review of work on, 230.
Recto-vaginal fistules, remarks on, 433.
Rectum, glass bottle in, 252; polypus of, 317.
Rhyncosa excavata, properties of, 368.
Richardson, Dr. Joseph G., thermometry in diphtheria, 217.
Roberts, Dr. W. C., epidemic contagion, 165; cholera, 89.
Rockwell, Dr. A. D., medical use of electricity, 1, 98, 148, 169, 361, 409, 486.
Rogers, Dr. S., extra-uterine fœtation, 22; letter from, 263; protective use of quinine, 292.
Roosa, Dr. D. B. St. John, clinical papers on ear diseases, 339, 460.
Rubeola, peculiar form of eruption in, 228.

Rush Medical College, Chicago, 383.

S.

Sacro-iliac junction, caries of, 88.
Salisbury, Dr. J. H., stelline, 529.
Sayre, Dr. L. A., letters from, 359, 452.
Scarlet fever, remarks on, 91, 260, 363, 441.
Scapula, removal of, 491.
Schmid, Dr. H. E., atomized lime-water in croup, 78.
Scrofulosis, remarks on, 56, 79, 102, 370.
Scrotum, restoration of after sloughing, 269.
Sea-sickness, remarks on, 337.
Seguin, Dr. E., ether versus chloroform, 44.
Semilunar valves, rupture of, 283.
Sexes, production of at will, 24.
Sexual organs, review of work on, 17.
Shaffer, Dr. N. M., letter from, 311.
Shaw, Dr. H. L., aural catarrh, 27.
Shock, advantage of position in, 346.
Shoulder, old dislocations of, new method of reducing, 235.
Sigmoid flexure, cancer of, 399.
Skin, some points in the anatomy and physiology of the, 73.
Smith, Dr. J. Lewis, infantile apoplexy, 112; pleurisy in infant, 19.
Smith, Dr. Nathan R., review of work by, 255.
Societies, publication of reports of, 234.
Sound, effect of absence of on mind and hearing, 432.
South, congestive fever in the, 215.
Specialism and general medicine, 517.
Speculum, description of a self-retaining, 481.
Sphygmograph, cautions in regard to use of, 59.
Spine, review of work on, 111.
Splanchnoscopy, remarks on, 468.
Spleen, enlarged, diagnosis of, 273.
Spurious vaccination, review of work on, 183.
Stelline and stellurine, 529.
Stiles, Dr. R. C., herpes circinatus from achorion in mouse, 340.
Stirling, Dr. T. B., rupture of vagina in labor, 510.
Strabismus, modification of, the operation for, 11.
Stricture, effects of, 571.
Strychnine poisoning treated by chloroform, 22.
Stomach-pump, substitute for the, 192.
Stomach, probable gunshot wound of, 497.
Stone, Dr. Warren, on yellow fever, 364.
Suture, new form of, 204.
Sulphur in croup, 372.
Sweating, sage tea for, 336.
Subclavian aneurism, case of, 233; ligature of, 97, 412.
Syme's amputation, value of, 40.
Synovitis, electricity in, 148.
Syphilis, mercury in, 304.
Syphilographers, incidents concerning, 307.

T.

Tænia, new method for expelling, 441.
Tannin as a hæmostatic, 372, 392.
Taylor, Dr. C. F., nitrous oxide as an anæsthetic, 77; hip disease, 289.
Teeth, the reason for caries of, 171.
Teeth, artificial, new base for, 336.
Tendons, contracted, treatment of, 418.
Testicle, abnormal position of the, 303; cancer of, 207.
Tetanus, recoveries from, 442.
Therapeutics, review of work on, 568.
Thigh, new splint for fracture of, 500.
Thoms, Dr., alcohol, or fatality of cholera, 67; hereditary tendency to hæmorrhagic diathesis, 19.
Thomas, Dr. T. G., uterine pathology, 498.
Tobold, Dr. A., review of work by, 206.
Toes, lectures on certain affections of, 201.
Tonsillar concretion, a case of, 413.
Townsend, Professor Howard, death of, 45.
Tricuspid, direct murmur, 259.
Trichiniasis and its effects on an unbeliever, 503.
Trichinosis, nature of, 83.
Trichinæ, weight of, 480.
Trousseau, death of, 264.
Tsa-Tsin, as an emmenagogue, 368.
Tubercle, inoculability of, 108, 572.
Tuberculosis, lectures on, 56, 79, 102.
Tumors, lectures on, 487, 512; abdominal, difficulties in the diagnosis of, 369; electrolytic treatment of, 108; removal of deep cervical, 173.
Turkish baths, some ideas concerning their utility, 117.
Turner, Dr. W. Mason, vesical calculus, 460; anaphrodisia, 297; sea-sickness, 337.
Typhus fever treated with tea, 264.
Typhoid fever, a diagnostic and prognostic sign in, 156.

U.

Ulna, luxation of, 263, 310, 387.
University of Pennsylvania, reports from, 413.
University of Washington, account of, 408.
Urea, source of, 94.
Urethra, discharge of worm through, 174.
Urethritis, starch injections in, 394.
Urinary calculi, 330; organs, pathology of, 506.
Urine, extensive diabetic, examination of, 180; extravasation of urine, 415.
Uterine; applicator, 478; disease at conception, 259; element in practice, 205, 262, 286, 332; elevator, a new, 115; pathology, history of, 499; pessary, description of a new, 428.
Uterus, adventitious growths in, 78; extirpation of, 36, 297, 393, 505; fibrous tumors of, 52, 570; laceration of by sound, 499; present raid on the, 455; inverted action of, 556.
Uvula, treatment for relaxed, 84.

V.

Vaccination cicatrices and revaccination, 563.
Vagina, rupture of, during labor, 510.
Varick, Dr. T. R., lateral luxation of radius and ulna outward, 387.
Variola, preventing pitting in, 391.
Velpeau, obituary notice of, 333.
Ventilation, active, 359.
Ventricle, left, rupture of, 185.
Vermont Medical Society, review of transactions of, 159.
Vesical calculus, case of, 460.
Vesico-intestinal fistula, 208.
Vesico-vaginal fistula, remarks on, 433.
Vinegar to detect sulphuric acid in, 71.
Volume II. of MEDICAL RECORD, close of, 565.

W.

Warren, Dr. J. M., obituary notice of, 334.
Watts, Dr. Robt., obituary notice of, 404, 454, 479.
Weaning, practical remarks on, 371.
Wells, Mr. T. Spencer, visit of, 350; ovarian tumors, 356.
Wet-nursing, mortality attending, 61.
White, Dr. F. V., fracture of patella, 198, 221.
Whitehead, Dr. W. R., treatment of delirium tremens, 340; osseous tumor of jaw, 145.
Wilson, Dr. G., restoration of scrotum from sloughing, 269.
Wistar, Dr. Caspar, obituary notice of, 119.
Woman's Hospital, New York, account of, 404.
Wood, Dr. George B., review of work by, 568.
Wood, Dr. James R., reproduction of bone, 269.
Wormley, Dr. Theo. G., review of work by, 425.
Worms, discharge of through urethra, 174.
Wright, Dr. H. G., review of work by, 568.

Y.

Yellow fever, remarks on, 321, 327, 364, 374.

Z.

Zinci chloridi liquor, in gonorrhœa, 381, 427.
Zymotic diseases, present state of knowledge regarding, 344.

The attention of Physicians is requested to

COLE'S IMPROVED BREAST-PUMP.

PATENTED DEC. 24, 1867.

The inventor has received abundant testimony as to its efficiency and superiority, agreeing substantially with the following:

From T. F. COCK, M.D., 13 *West Thirty-sixth St., Sept.* 17, 1866.

"MR. JAMES COLE—*Sir:* I have given your Improved Breast-Pump several trials, and am pleased with its performance. *Experienced nurses assured me that it acted better than other instruments for the same purpose.*"

From T. GAILLARD THOMAS, M.D., *Professor of Obstetrics, College of Physicians and Surgeons, N. Y.*

"I have employed Cole's Breast-Pump in my practice with much satisfaction. It is simple, *painless in its operation, and very efficient.* It imitates in its principle the action of the child's mouth in sucking."

From G. MILIANO, 24 *West Eleventh St., June* 12, 1866.

"I have tried Cole's Improved Breast-Pump in several unfavorable circumstances, where other breast-pumps had failed to fulfil the desired objects. I find it a simple but effective contrivance.

Sold by all druggists.

LORD, MCNARY & CO., *General Agents,*
22 Vesey street, New York.

Sent Free by Mail on Receipt of Price,

Nature in Disease; Illustrated in Various Discourses and Essays, to which are added Miscellaneous Writings, chiefly on Medical Subjects. By JACOB BIGELOW, M.D., Professor of Materia Medica in Harvard University, etc., etc. 2d edition. One neat 12mo. volume. Extra cloth, $1.25.

PROSPECTUS

OF THE

SAINT LOUIS MEDICAL REPORTER,

A Semi-Monthly Record of Medicine and Surgery.

EDITED BY J. S. B. ALLEYNE, M.D.,

Professor of Materia Medica in the St. Louis Medical College,

AND

O. F. POTTEN, M.D.,

Professor of Materia Medica in the St. Louis College of Pharmacy.

This periodical is published on the 1st and 15th of every month, and will contain not less than thirty-two pages in each number, making a volume of nearly eight hundred pages per annum.

The pages of the REPORTER will be devoted to Original Communications on the general and special departments of Medicine, Surgery, Dentistry, and the Collateral Sciences. Transactions of Societies, Reviews and Notices of Books and Publications, Hospital Reports and reports of special cases of interest, judicious selections from other journals, and a general summary of foreign and domestic intelligence in the several branches of Medical Science, together with editorial comments and scientific news.

Communications are solicited from all parts of the country. The REPORTER has been published for over two years, and has the largest circulation of any medical periodical ever published in St Louis. We especially invite the attention of Publishers, Druggists, and those dealing in Medical Merchandise to our work as a Superior Advertising Medium, and our rates are as low as any in the West.

SUBSCRIPTION PRICE.

One copy per annum, invariably in advance.....$ 3 00
Or two copies per annum " " 5 00
Specimen Copies sent on application.
Reporter and New York Medical Record, one year..... 6 00

FACULTY.

AUSTIN FLINT, M.D., Professor of Clinical Medicine.

FRANK H. HAMILTON, M.D., Professor of Principles and Practice of Surgery, of Fractures and Dislocations, and Military Surgery.

DE WITT C. ENOS, M.D., Professor of Operative and Clinical Surgery.

AUSTIN FLINT, JR., M.D., Professor of Physiology and Microscopic Anatomy.

DARWIN G. EATON, M.D., Professor of Chemistry and Toxicology.

WILLIAM GILFILLAN, M.D., Professor of Surgical Anatomy.

SAMUEL G. ARMOR, M.D., Professor of Principles and Practice of Medicine and Materia Medica.

CORYDON L. FORD, M.D., Professor of Anatomy.

FOSTER SWIFT, M.D., Professor of Obstetrics and Diseases of Women and Children.

The *Ninth Regular Term of Lectures* will commence in the Hospital buildings, corner of Henry and Pacific streets, on the first of March, 1868, and end in July. For circulars or information with reference to the College, address T. L. Mason, M.D., President, 120 Joralemon street; William H. Dudley, M.D., Registrar, 201 Henry street; or C. L. Mitchell, M.D., 77 Montague street.

Fees: Professors' tickets, $140; Matriculation, $5; Dissecting, $10; Graduation, $25; Hospitals, *free.*

DR. TAYLOR'S

ORTHOPÆDIC APPARATUS.

In consequence of numerous inquiries, we would announce to the profession, that we have made arrangements to furnish from our private workshop any of the Apparatus used in the New York Orthopædic Institution.

These Instruments are nearly all original inventions of Dr. TAYLOR, and embrace appliances for Angular and Lateral Curvature of the Spine; for Talipes in its various forms; for Morbus Coxarius, and for most other deformities and diseases of the joints.

We wish it to be understood, however, that we shall receive no orders except for instruments above named, nor for them, unless from some knowledge of the case we can know that their use is properly indicated.

TAYLOR & VERMILYE,
1303 Broadway, New York.

Sent Free by Mail on Receipt of Price.

The Uræmic Convulsions of Pregnancy, Parturition, and Child-bed. By CARL R. BRAUN, M.D., Professor of Midwifery, Vienna. Translated from the German, with notes by J. M. Duncan, M.D. One neat 12mo. volume. Price $1.00.

"We advise all who feel interested in the subject, to procure it, as it will fully repay the perusal."—*St. Louis Medical and Surgical Journal.*

BELLEVUE HOSPITAL MEDICAL COLLEGE.

CITY OF NEW YORK.

Sessions 1867—1868.

The COLLEGIATE YEAR in this Institution embraces a Preliminary Autumnal Term, the Regular Winter Session, and a Summer Session.

The PRELIMINARY AUTUMNAL TERM for 1867–68 will commence on Wednesday, September 18, 1867, and continue until the opening of the Regular Session.

The REGULAR SESSION will commence on Wednesday, October 16, 1867, and end about the first of March, 1868. Instruction during the Preliminary Term will, as hitherto, consist of didactic lectures on special subjects, and daily clinical lectures. The lectures in this term are given exclusively by members of the Faculty. Students designing to attend during the Winter Session are strongly recommended to attend during the Preliminary Term, but attendance during the latter is not required.

The SUMMER SESSION will commence on the second Wednesday in March, and continue twelve weeks. This term will embrace courses of didactic lectures by the members of the Faculty of the Summer Session, together with clinical lectures at Bellevue Hospital, and the Charity Hospital, Blackwell's Island, and the daily recitations. Lectures will also be given by members of the College Faculty.

FACULTY OF THE COLLEGE.

ISAAC E. TAYLOR, M.D., President, and Emeritus Professor of Obstetrics.

JAMES R. WOOD, M.D., Professor of Operative Surgery and Surgical Pathology.

FRANK H. HAMILTON, M.D., Professor of Military Surgery, Fractures and Dislocations, and the Principles of Surgery.

LEWIS A. SAYRE, M.D., Professor of Orthopedic Surgery.

ALEXANDER B. MOTT, M.D., Professor of Surgical Anatomy.

W. H. VAN BUREN, M.D., Professor of Diseases of the Genito-Urinary System.

GEORGE T. ELLIOT, M.D., } Professors of Obstetrics and the Dis-
FORDYCE BARKER, M.D., } eases of Women and Children.

BENJAMIN W. McCREADY, M.D., Professor of Materia Medica and Therapeutics.

STEPHEN SMITH, M.D., Professor of Descriptive and Comparative Anatomy.

AUSTIN FLINT, M.D., Professor of the Principles and Practice of Medicine.

R. OGDEN DOREMUS, M.D., Professor of Chemistry and Toxicology.

AUSTIN FLINT, JR., M.D., Professor of Physiology and Microscopy.

WILLIAM A. HAMMOND, M.D., Professor of Diseases of the Mind and Nervous System.

N. R. MOSELY, M.D., Demonstrator of Anatomy.

J. W. SOUTHACK, JR., M.D., Assistant Demonstrator of Anatomy.

FACULTY OF THE SUMMER SESSION.

HENRY D. NOYES, M.D., Professor of Ophthalmology, and Dean of the Summer Faculty.

J. LEWIS SMITH, M.D., Professor of Morbid Anatomy.

FOSTER SWIFT, M.D., Professor of Diseases of the Skin.

PROF. W. H. VAN BUREN, M.D., Lecturer on Diseases of the Genito-Urinary System.

PROF. R. OGDEN DOREMUS, M.D., Lecturer on Animal Chemistry.

PROF. AUSTIN FLINT, JR., M.D., Lecturer on Microscopical Anatomy.

PROF. GEORGE T. ELLIOT, M.D., Lecturer on the Diseases of Children.

PROF. WILLIAM A. HAMMOND, M.D., Lecturer on Diseases of Nervous System.

A distinctive feature of the method of instruction in this College, is the union of clinical and didactic teaching. All the lectures are given within the Hospital grounds. During the Regular Winter Session, in addition to four didactic lectures on every week-day, except Saturday, two or three hours are daily allotted to clinical instruction. The union of clinical and didactic teaching will also be carried out in the Summer Session, the teachers in this Faculty being physicians and surgeons in the great Charity Hospital on Blackwell's Island.

FEES FOR THE REGULAR SESSION.

Fees for tickets to all the lectures during the Autumnal and the Regular Winter Session, including clinical lectures	$140.00
Tickets for any of the several departments may be taken out separately.	
Matriculation fee	5.00
Demonstrator's Ticket (including material)	10.00
Graduation fee	30.00

Students who have attended two full courses in other accredited schools receive all the tickets for $70, exclusive of the Matriculation Fee. Students who have attended two full courses in this College, or after one full course in this College, having previously attended a full course in some other accredited schools, are required to matriculate only. Graduates of other accredited schools, after three years, dating from the time of graduation to the end of the term, are required to matriculate only; prior to three years, they receive a general ticket for $70.

FEES FOR THE SUMMER SESSION.

Matriculation (valid for the succeeding Winter Session)	$5.00
For each of the separate courses of lectures	10.00
General Ticket admitting to all the lectures	50.00

Graduates of the Bellevue Hospital Medical College will be admitted to the lectures of the Summer Session on the Matriculation ticket; all others will be required to take out tickets.

☞ The dissecting-room will be kept open until about the first of May.

Payment of Fees is invariably required at the commencement of the Session. There are no exceptions to this rule.

Students, on arriving in the city, are requested to report at once at Bellevue Hospital, situated on the East River, between Twenty-sixth and Twenty-eighth streets, and inquire for the Janitor of the College, who will take pains to aid them in securing comfortable accommodations without delay. Entrance to the Hospital is on Twenty-sixth street.

For the Annual Circular and Catalogue, giving regulations for graduation and other information, address the Secretary of the College, Prof. AUSTIN FLINT, JR., Bellevue Hospital Medical College.

For Circular giving information concerning the Summer Session, address the Secretary of the College, or Prof. HENRY D. NOYES, No. 68 Madison Avenue, Dean of the Summer Faculty.

COLLEGE OF PHYSICIANS AND SURGEONS,

Corner of Twenty-third Street and Fourth Avenue, New York.

SIXTY-FIRST SESSION, 1867-68.

FACULTY OF MEDICINE.

EDWARD DELAFIELD, M.D., President and Professor Emeritus of Obstetrics.
WILLARD PARKER, M.D., Professor of the Principles and Practice of Surgery and Surgical Anatomy.
THOMAS M. MARKOE, M.D., Professor Adjunct of Surgery.
ALONZO CLARK, M.D., Professor of Pathology and Practical Medicine.
JOHN T. METCALFE, M.D., Professor of Clinical Medicine.
JOHN C. DALTON, M.D., Professor of Physiology and Microscopic Anatomy.
SAMUEL ST. JOHN, M.D., Professor of Chemistry.
T. GAILLARD THOMAS, M.D., Professor of Obstetrics and the Diseases of Women and Children.
HENRY B. SANDS, M.D., Professor of Anatomy.
FREEMAN J. BUMSTEAD, M.D., Professor of Venereal Diseases.
D. TILDEN BROWN, M.D., Lecturer on Psychological Medicine and Medical Jurisprudence.
JAMES W. McLANE, M.D., Lecturer on Materia Medica.
ERSKINE MASON, M.D., Demonstrator of Anatomy.
GEORGE G. WHEELOCK, M.D., Assistant Demonstrator.

IN THE PLAN OF INSTRUCTION adopted in this Institution, Clinical Teaching constitutes an important and prominent feature, all the practical subjects treated of in the Didactic Course being fully illustrated at the bedside. In the furtherance of this object, the extensive Hospitals of New York, of which the New York Hospital, the Bellevue Hospital, the Charity Hospital, Blackwell's Island, and the New York Eye Infirmary, are the largest and most efficient, furnish ample fields for instruction and study.

To all of these the Faculty of the College resort for the purposes of practical instruction, Cliniques being held daily in one or more of them:

In the Bellevue Hospital, by Professors CLARK, MARKOE, METCALFE, THOMAS, and SANDS.
In the New York Hospital, by Professors MARKOE and SANDS.
At the Charity Hospital, Blackwell's Island, by Prof. BUMSTEAD and Dr. MASON.
At the New York Eye Infirmary, by Dr. MASON.

Besides the Clinical Lectures given at the Hospitals, as above, there are seven Cliniques each week, at the College Building, viz.:

Surgical Clinique, by Prof. MARKOE, every Monday at 12 M.
Medical Clinique, by Prof. CLARK, every Thursday at 12 M.
Surgical Clinique, by Prof. DETMOLD, every Wednesday at 3 P.M.
Venereal Clinique, by Prof. BUMSTEAD, every Monday at 3 P.M.
Ophthalmic Clinique, by Dr. AGNEW, every Tuesday at 3 P.M.
Clinique for Diseases of Skin, by Dr. DRAPER, every Thursday at 3 P.M.
Female Clinique, by Prof. THOMAS, every Friday at 3 P.M.

REGULAR COURSE.

IN PRACTICAL OBSTETRICS, each advanced student in the College has one or more cases assigned to his *exclusive* care, and may thus become practically familiar with this important branch, in all its details. Should any abnormal or difficult case occur, the student has the privilege of sending for the Professor of Obstetrics, who then takes charge of the patient and embraces the opportunity of giving clinical demonstrations of the most approved method of treatment.

THE PURSUIT OF PRACTICAL ANATOMY is provided for, in the College, by a large and commodious apartment, admirably lighted and ventilated, and abundantly supplied with gas and Croton water. It will be opened early in October, and continue open until the following April.

Material for dissection is supplied in abundance, and at a very low rate; so that every student can go through with a thorough course of dissection.

There are also abundant facilities, connected with the College, for the pursuit of special studies, by PRIVATE COURSES, under competent instructors, and for Private Examinations on the subjects treated in the public lectures, of which the student may avail himself, as his inclination and advantage may dictate.

Matriculation Fee, $5; Fees for the full Course of Lectures by all the Professors, $140; for each separate ticket, $20; tickets of the Demonstrator of Anatomy, $10; Graduation Fee, $30.

The Tickets are to be taken at the beginning of the Session.

Students who have attended two full courses in this College, or who, having attended one full course in some regularly established medical school, shall *subsequently* attend one full course in this College, are admitted to a third course of lectures on paying the matriculation fee only.

Graduates of this school are admitted without fee. Graduates of other regular schools, who have been in practice three years, and *Theological Students*, are admitted on general ticket, by paying the matriculation fee.

Recent Graduates of other regular schools, and students who have already attended two full Courses of Lectures, are admitted to this College on payment of the Matriculation Fee and $70.

Letters requiring information should be directed to the Secretary of the Faculty, College of Physicians and Surgeons, corner of Twenty-third Street and Fourth Avenue, New York.

Students are requested, on their arrival in the city, to call at the College and register their names with the Clerk, Mr. Denham, who will give them all necessary information, and aid them in obtaining board.

MEDICAL DEPARTMENT

OF THE

UNIVERSITY OF VERMONT,

AND

STATE AGRICULTURAL COLLEGE,

BURLINGTON, VERMONT.

FACULTY.

JAMES B. ANGELL, A.M., President.

SAMUEL WHITE THAYER, M.D., Professor of General and Special Anatomy.
WALTER CARPENTER, M.D., Professor of Theory and Practice of Medicine and Materia Medica.
JOSEPH PERKINS, M.D., Professor of Obstetrics and Diseases of Women and Children.
HENRY M. SEELY, M.D., Professor of Chemistry and Toxicology.
JOHN ORDRONAUX, M.D., Professor of Physiology and Pathology.
ALPHEUS B. CROSBY, M.D., Professor of Principles and Practice of Surgery.
CHARLES PAINE THAYER, M.D., Demonstrator of Anatomy.
S. W. THAYER, Burlington, Dean of Medical Faculty.

The next Annual Course of Lectures in this Institution will commence on the first Thursday of March, 1868, and continue sixteen weeks. At the commencement of the term, every student is required to call on the Dean, enter his name and register, and pay all fees for the course.

Fees.—The fees of the College have been raised, in common with the other Medical Colleges in this Country.

Matriculation (paid but once)	$ 5 00
Dean's Certificate (general Ticket)	70 00
Graduation Fee	25 00

Students who have attended two full courses of Lectures in other accredited Medical Colleges, receive all the Tickets to the Lectures of this College, exclusive of the Matriculation Ticket, for $20.

On Saturday of each week, a Medical and Surgical Clinique will be held at the College.

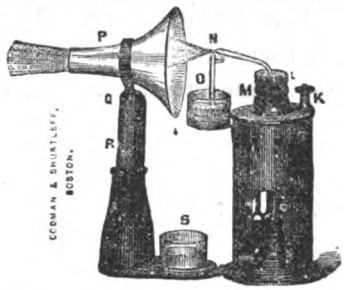
The Dissecting Room will be open through the term. An ample supply of anatomical material will be furnished at cost.

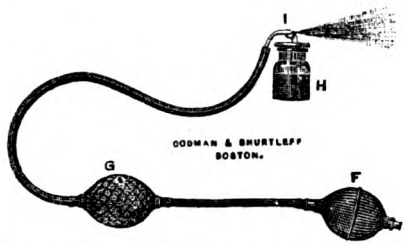
For further information, address

S. W. THAYER, M.D., *Dean,*
Burlington, Vermont.

CODMAN & SHURTLEFF'S

Apparatus for Local Anæsthesia and Atomization of Liquids.





☞ Will be sent by mail (post-paid), on application,

A PAMPHLET,

containing two articles by distinguished foreign authority, on

"INHALATION OF ATOMIZED LIQUIDS,"

with formulæ of those successfully employed.

An article by Dr. J. L. W. THUDICHUM, M. R. C. P., on

"A NEW MODE OF TREATING DISEASES OF THE NASAL CAVITY,"

with his formulæ.

An illustrated description of the *best apparatus* for the above purposes, and for producing Local Anæsthesia by Atomization, with Ether, by the method of Dr. RICHARDSON of London; or with Rhigolene, as described by Dr. HENRY J. BIGELOW, in the *Boston Medical and Surgical Journal* of April 19, 1866. The following is an extract from a note from Dr. Bigelow:—

"I have thus far found nothing better for freezing with Rhigolene than the tubes made by you after the pattern I gave you, and which I still use with your other apparatus."

Dr. J. MASON WARREN says:—

"Your apparatus for Atomization of Liquids seems to have been carefully made, and I think it an efficient one where required for treatment of diseases of the Throat and Lungs. The apparatus for Local Anæsthesia which you made for me answers the purpose perfectly."

☞*A GOLD MEDAL has lately been awarded us by the Middlesex Mechanics' Association, for Atomizing and Surgical Instruments.*

PRICES.

Steam Apparatus complete, with two Glass Atomizing Tubes and Face Shield, packed for transportation $12.00

Hand Ball Apparatus, with two Glass Atomizing Tubes for Inhalation, and one Metal Tube for Local Anæsthesia, packed 6.00

Rhigolene for Local Anæsthesia, best quality, packed 1.00

Nasal Douche, or Apparatus of Dr. THUDICHUM for treating Diseases of the Nasal Cavity, packed . . . . . 2.50 to 3.50

[For complete illustrated price-list of the above see pamphlet.]

[SEE OTHER SIDE OF LEAF.

Our Atomizing Apparatus is made with the utmost care with view to its complete efficiency, convenience, and durability, and every one is warranted. The Steam Apparatus has been adopted into the "Supply Table," as the standard for the United-States Army. The parts of each kind being interchangeable, physicians at a distance can be sure that in ordering tubes, &c., they will be adapted to the apparatus previously purchased.

PRICE-CURRENT OF

CONCENTRATED MEDICINES,

CONCENTRATED TINCTURES, ETC.,

PREPARED AT THE LABORATORY OF

B. KEITH & CO., NEW YORK.

CONCENTRATED MEDICINES; OR, ACTIVE PRINCIPLES OF MEDICINAL PLANTS.

The list embraces many preparations from Crude materials of recognized officinal medicinal value. Others, though comparatively new to the profession, are fast gaining confidence in their remedial powers.

Each preparation represents the full therapeutic virtues of the crude substance from which it is derived.

They are *definite* in constitution and therapeutic power, *uniform* in medicinal strength, *reliable* in clinical practice, and *not liable* to vary, change, or deteriorate by age.

We prepare no lactinated articles, nor triturations with foreign substances of any kind.

They are put up in bottles of one ounce avoirdupois, and securely sealed to protect them from the action of the atmosphere.

CONCENTRATED TINCTURES.—These tinctures are among the greatest improvements in modern pharmacy, and embrace the peculiar features for which our preparations have become so celebrated. They combine the essential qualities of definiteness, uniformity, and reliability. The various proximate active principles are isolated singly, divested of all non-medicinal admixture, carefully estimated and redissolved in alcohol in exact proportions. Hence, they resemble a definite solution of Morphia, Quinia, or any other definite vegetable alkaloid, and invariably represent a uniform amount of therapeutic power. They are concentrated, definite solutions of the entire medicinal constituents of the plants from which they are severally derived.

They are much Stronger than any other Fluid Preparations made from the same Articles.

Colomba	ʒ 1
Gentian Lutea	ʒ 2
Absinthium Art.	ʒ 1
Cinchon. Pulv.	ʒ 4
Galanga	gr. 24

HYGIENIC WINE is manufactured in Paris, from a pure Sherry, by an eminent chemist. A half century's care and experience have found those proportions of ingredients which combine the most improved tonic principles with excellence of flavor; thus not only rendering it valuable as a tonic, but also desirable as a beverage.

Hygienic Wine contains no alcoholic or whiskey admixture whatever, and is consequently not intoxicating. Its stimulating power is gentle but most effectual; it is an admirable appetizer, and excellent for dyspepsia, and all derangements of the digestive organs. It is nutritious from the fruity wine which is its base. Hygienic Wine has received the approval of the Pharmaceutical School of France. The most eminent physicians in Europe recommend it in their daily practice, and it is found in constant use by the enlightened classes of people in Europe.

A Tonic Wine requiring such skill in its preparation has been greatly needed, and Hygienic Wine is submitted for approval to fill this want, and will, upon trial, undoubtedly be found to possess all that is claimed for it.

An extract from an article in the "Home Journal," of May 1, 1867, on Wines, may appropriately be introduced in this connection:

"And without doubt, a careful preparation having a pure wine for its base, in which a proportion of these tonics (named before) is scientifically infused, would be a beverage as beneficial for family use as for the physician. * * * The tissues in contact with the nutritious blood have a tendency to appropriate to themselves the elements most proper to maintain their healthy condition, or to alter it when unhealthy. The hygienic virtues of such a wine cannot be over-estimated."

It is put up handsomely in large-sized clarets, and retails at the very low price of $1.50 per bottle.

You are respectfully solicited to try one case, feeling confident that you will be as well pleased with it as others who have tried it.

TO THE MEDICAL FACULTY.

It would be a work of supererogation to call the attention of the Profession to the utility of Saline Febrifuges and Purgatives in a large class of diseases. Its members are well aware (to use the language of Dr. John Bell, one of the most distinguished pathologists and surgeons of modern times) that "of all the prescriptions made up with a view to alterative effect, none can be compared with Mineral Waters."

This being the case, we have no hesitation in recommending

TARRANT'S EFFERVESCENT SELTZER APERIENT

to the favorable consideration of physicians and surgeons. Its composition is based on a qualitative and quantitative analysis of the water of the celebrated Seltzer Spring, of which it contains all the essential ingredients in their due proportions, without any of the inert matter found in the material fluid. It is believed to be the best Saline Aperient and Alterative known, and is considered by eminent members of the Profession a valuable medicine in all phases and types of disease to which preparations of this class are adapted. As a means of alleviating all maladies in tropical climates it has been found peculiarly valuable.

Physicians presiding over or attached to hospitals and other public institutions, and the medical staff of the army and navy, are particularly requested to test the sanitary properties of the preparation.

Very respectfully,

TARRANT & CO.,

278 Greenwich street, New York.

The Best Three Tonics of the Pharmacopœia,

IRON, PHOSPHORUS, AND CALISAYA.

CASWELL, HAZARD & CO. call the attention of the Profession to their preparation of the above estimable Tonics, as combined in their elegant and palatable

Ferro-Phosphorated Elixir of Calisaya Bark.

Each teaspoonful of the Elixir contains one grain of the Salt of Phosphorus and Iron, and each pint contains one ounce of Royal Calisaya Bark.

The Profession are warned against many imitations of the Ferro-Phosphorated Elixir of Calisaya, made from very inferior materials, and by unprincipled persons.

HAZARD & CASWELL'S

PURE COD-LIVER OIL.

This Oil is confidently recommended to the trade and Medical Profession as the SWEETEST and PUREST in market.

It is made of fresh selected livers on the seacoast, and can be retained by the stomach when other kinds fail, so sweet and pure is it, from the great care and skill attending its manufacture.

The nauseous and offensive character of the usual Cod Liver Oil in use, is extremely prejudicial—more so than none at all—so that an article fresh and pure is indispensable.

Professor Parker, of New York, says: "I have tried almost every other manufacturer's Oil, and give yours the decided preference."

Professor Hayes, State Assayer of Massachusetts, after a full analysis of it, says: "It is the best for foreign or domestic use."
